The temperature and density of water affect the speed at which sound waves travel through it, and allowances have to be made for variations in these properties. The reflected signals are recorded several times a second on a moving strip of paper, showing to scale the depth beneath the ship's track. The echoes may also show other objects, such as schools of fish, or they may reveal the dual nature of the bottom, where a layer of soft mud may overlie rock. Originally only the depth that was directly beneath the ship was measured, leaving gaps between the ship's tracks. Later inventions, which include sideways-directed sonar and television cameras, have made it possible to fill these gaps. While measurements of depths away from the ship's track are not so accurate, the pictures reveal any dangerous objects such as rock pinnacles or wrecks, and the survey vessel can then be diverted to survey them in detail.

Modern position-fixing techniques using radar have made the whole process much simpler, for the ship's location is now known continuously with reference to fixed stations on shore or to satellite tracks. Another modern technique is the use of pictures taken from aircraft or satellites to indicate the presence and shape of shoal areas and to aid the planning of their detailed survey.

An alternative to the use of radar or satellite signals for continuous and automatic recording of a ship's position is the employment of inertial guidance systems. These devices, developed to satisfy military requirements, detect every acceleration involved in the motion of a craft from its known starting point and convert them and the elapsed time into a continuous record of the distance and direction traveled.

For studying the seabed in detail, the bottom of the sounding lead was hollowed to hold a charge of grease to pick up a sample from the sea floor. Today television cameras can be lowered to transmit pictures back to the survey ship, though their range is limited by the extent to which light can penetrate the water, which often is murky. Ordinary cameras also are used in pairs for making stereoscopic pictures of underwater structures such as drilling rigs or the wreckage of ancient ships.

Height determination. Heights of surface features above sea level are determined in four main ways: by spirit leveling, by measuring vertical angles and distances, by measuring differences in atmospheric pressure, and, since the late 20th century, by using three-dimensional satellite or inertial systems. Of these the first is the most accurate; the second is next in accuracy but faster; the third is least accurate but can be fastest if heights are to be measured at well-separated points. The last two techniques require sophisticated equipment that is still very expensive.

Spirit leveling

In spirit leveling the surveyor has for centuries used a surveying level, which consists of a horizontal telescope fitted with cross hairs, rotating around a vertical axis on a tripod, with a very sensitive spirit level fixed to it; the instrument is adjusted until the bubble is exactly centred. The reading on a graduated vertical staff is observed through the telescope. If such staffs are placed on successive ground points, and the telescope is truly level, the difference between the readings at the cross hairs will equal that between the heights of the points. By moving the level and the staffs alternately along a path or road and repeating this procedure, differences in height can be accurately measured over long horizontal distances.

In the most precise work, over a distance of 100 kilometres the error may be kept to less than a centimetre. To achieve this accuracy great care has to be taken. The instrument must have a high-magnification telescope and a very sensitive bubble, and the graduated scale on the staff must be made of a strip of Invar (an alloy with a very small coefficient of thermal expansion). Moreover, the staffs must be placed on pegs or special heavy steel plates, and the distance between them and the level must always be the same to cancel the effects of aerial refraction of the light.

In less precise work a single wooden staff can be used; for detailed leveling of a small area, the staff is moved from one point to another without moving the level so that heights can be measured within a radius of about 100 metres (Figure 18). The distances of these points from the instrument can be measured by tape or, more commonly, by recording not only the reading at the central cross hair in the field of view of the telescope but also those at the stadia hairs, that is by tachymetry, as described above. The bearing of each point is observed by compass or on the horizontal circle of the level so that it can be plotted or drawn on the map.

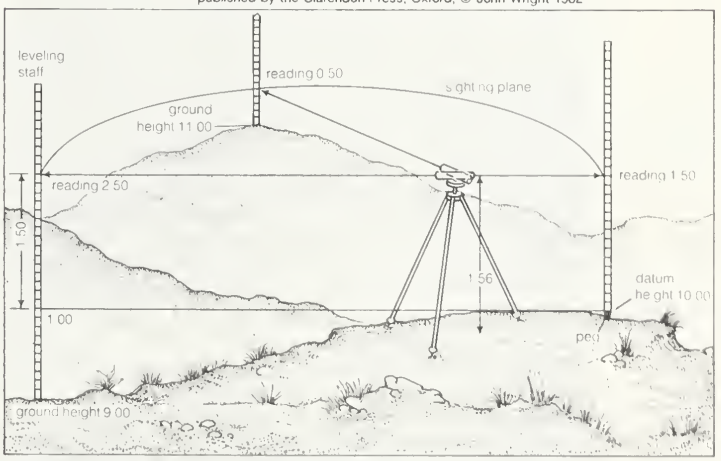

Figure 18: Spirit leveling to measure heights of ground points relative to that of a datum point (see text).

Since the 1950s levels have been introduced in which the line of sight is automatically leveled by passage through a system of prisms in a pendulum, thus removing the need to check the bubble. The disadvantage of spirit leveling is the large number of times the instrument has to be moved and realigned, particularly on steep hills; it is used primarily along practically flat stretches of ground.

For faster work in hilly areas, where lower accuracies usually are acceptable, trigonometric height determination is employed using a theodolite to measure vertical angles and measuring or calculating the distances by triangulation. This procedure is particularly useful in obtaining heights throughout a major framework of triangulation or traverse where most of the points are on hilltops. To increase precision, the observations are made simultaneously in both directions so that aerial refraction is eliminated; this is done preferably around noon, when the air is well mixed.

The third method of height determination depends on measurements of atmospheric pressure differences with a sensitive aneroid barometer, which can respond to pressure differences small enough to correspond to a foot or two (0.3 to 0.6 metre) in height. The air pressure changes constantly, however, and to obtain reliable results it is necessary to use at least two barometers; one at a reference point of known height is read at regular intervals while the surveyor proceeds throughout the area, recording locations, times, and barometer readings. Comparison of readings made at the same time then gives the height differences.

An alternative to the barometer for pressure measurement is an apparatus for measuring the boiling point of a liquid, because this temperature depends on the atmospheric pressure. Early explorers determined heights in this way, but the results were very rough; this technique was not accurate enough for surveyors until sensitive methods for temperature measurement were developed. The airborne profile recorder is a combination of this refined apparatus with a radar altimeter to measure the distance to the ground below an aircraft.

Analysis of the signals received simultaneously from several satellites gives heights as accurately as positions. Heights determined in this way are useful in previously unmapped areas as a check on results obtained by faster relative methods, but they are not accurate enough for mapping developed areas or for engineering projects. All-terrain vehicles or helicopters can carry inertial systems accurate enough to provide approximate heights suitable for aerial surveys of large areas within a framework of points established more accurately by spirit leveling.

BIBLIOGRAPHY

History of mapping and surveying: A list of sources on the topic is presented in WALTER W. RISTOW, *Guide to the History of Cartography: An Annotated List of References on the History of Maps and Mapmaking* (1973). ROBERT C. DURU, *Maps and Map Making* (1977); and G.R. CRONE, *Maps and Their Makers: An Introduction to the History of Cartography*, 5th ed. (1978), are brief overviews. Essential aspects are explored in LEO BAGROW, *History of Cartography*, 2nd ed., rev. by R.A. SKELTON (1985, originally published in German, 1951); CHARLES BRICKER, *Landmarks of Mapmaking: An Illustrated Survey of Maps and Mapmakers* (1968; also published as *A History of Cartography: 2500 Years of Maps and Mapmakers*, 1969; reissued 1977); LLOYD A. BROWN, *The Story of Maps* (1949, reprinted 1979), and *Map Making: The Art That Became a Science* (1960); EDWARD LYNAM, *The Mapmaker's Art: Essays on the History of Maps* (1953); and JOHN NOBLE WILFORD, *The Mapmakers* (1981). Maps of specific periods are studied in CHARLES H. HAPGOOD, *Maps of the Ancient Sea Kings: Evidence of Advanced Civilization in the Ice Age*, rev. ed. (1979); R.A. SKELTON, *Decorative Printed Maps of the 15th to 18th Centuries* (1952, reprinted 1966); HUGH CORTAZZI, *Isles of Gold: Antique Maps of Japan* (1983); and RAYMOND LISTER, *How to Identify Old Maps and Globes: With a List of Cartographers, Engravers, Publishers, and Printers Concerned with Printed Maps and Globes from c. 1500 to c. 1850* (1965). The development of cartographic institutions can be traced in MARY BLEWITT, *Surveys of the Seas: A Brief History of British Hydrography* (1957); SIR ARCHIBALD DAY, *The Admiralty Hydrographic Service, 1795–1919* (1967); ADRIAN H.W. ROBINSON, *Marine Cartography in Britain: A History of the Sea Chart to 1855* (1962); and G.S. RITCHIE, *The Admiralty Chart: British Naval Hydrography in the Nineteenth Century* (1967).

Mapmaking: The procedures involved in creating a map are described in many books, including WELLMAN CHAMBERLIN, *The Round Earth on Flat Paper: Map Projections Used by Cartographers* (1947); ARTHUR D. MERRIMAN, *An Introduction to Map Projections* (1947); ERWIN J. RAISZ, *General Cartography*, 2nd ed. (1948), and *Principles of Cartography* (1962); EDUARD IMHOF, *Cartographic Relief Presentation* (1982; originally published in German, 1965); J.S. KEATES, *Cartographic Design and Production* (1973); ARTHUR H. ROBINSON *et al.*, *Elements of Cartography*, 5th ed. (1984); JOHN LOXTON, *Practical Map Production* (1980); and MORRIS M. THOMPSON, *Maps for America: Cartographic Products of the U.S. Geological Survey and Others*, 2nd ed. (1981). A range of special projects, of which cartography is an essential part, are described in A.H.A. HOGG, *Surveying for Archaeologists and Other Fieldworkers* (1980); TEODOR J. BLACHUT, ADAM CHRZANOWSKI, and JOUKO H. SAASTAMOINEN, *Urban Surveying and Mapping* (1979); P.F. DALE, *Cadastral Surveys Within the Commonwealth* (1976); S. ROWTON SIMPSON, *Land Law and Registration* (1976); R.A. SKELTON, *The Legal Elements of Boundaries and Adjacent Properties* (1930); CURTIS M. BROWN, WALTER G. ROBILLARD, and DONALD A. WILSON, *Evidence and Procedures for Boundary Location*, 2nd ed. (1981); T.W. BIRCH, *Maps: Topographical and Statistical*, 2nd ed. (1964, reprinted with corrections, 1976); B.W. LUCKE, *A Course on the Chart* (1966); M. CHRISS and G.R. HAYES, *An Introduction to Charts and Their Use*, 4th ed. (1977); and D.A. MOORE, *Marine Chartwork*, 2nd ed. (1981).

Technical developments: The many special studies in the field include CHESTER C. SLAMA (ed.), *Manual of Photogrammetry*, 4th ed. (1980); JOHN WRIGHT, *Ground and Air Survey for Field Scientists* (1982); C.D. BURNSIDE, *Electromagnetic Distance Measurement*, 2nd ed. (1982); and WILLIAM RITCHIE *et al.*, *Mapping for Field Scientists: A Problem-Solving Approach* (1977). Current developments are covered in special journals: *Surveying and Mapping* (quarterly); *Photogrammetria* (bimonthly); *Military Engineer* (bimonthly); *The American Cartographer* (semiannual); *Cartography* (semiannual); and *Cartographica* (quarterly).

Modern surveying: UNITED STATES. GOVERNMENT PRINTING OFFICE, *Surveying and Mapping* (1982), is a subject bibliography listing current sources. Informative introductory texts include WILLIAM C. WATTLES, *Land Survey Descriptions*, rev. ed., edited by GURDON H. WATTLES (1974); CHARLES A. HERUBIN, *Principles of Surveying*, 3rd ed. (1982); J.G. OLLIVER and J. CLENDINNING, *Principles of Surveying: Plane Surveying*, 4th ed. (1978); JERRY A. NATHANSON and PHILIP KISSAM, *Surveying Practice*, 4th ed. (1988); R.H. DUGDALE, *Surveying*, 3rd ed. (1980); and JACK C. MCCORMAC, *Surveying Fundamentals* (1983). Comprehensive treatments include CHARLES B. BREED and GEORGE L. HOSMER, *The Principles and Practices of Surveying*, 11th ed., rev. by W. FAIG, 2 vol. (1977); RAYMOND E. DAVIS *et al.*, *Surveying, Theory and Practice*, 6th ed. (1981); RUSSELL C. BRINKER and PAUL R. WOLF, *Elementary Surveying*, 7th ed. (1984); FRANCIS H. MOFFITT and HARRY BOUCHARD, *Surveying*, 7th ed. (1982); and G. BOMFORD, *Geodesy*, 4th ed. (1980). Instruments used in the practice are discussed in J. CLENDINNING and J.G. OLLIVER, *Principles and Use of Surveying Instruments*, 3rd ed. (1969, reissued 1972); and M.A.R. COOPER, *Modern Theodolites and Levels*, 2nd ed. (1982). Hydrography is the subject of A.E. INGHAM (ed.), *Sea Surveying*, 2 vol. (1975); and MELVIN J. UMBACH, *Hydrographic Manual*, 4th ed. (1976). INTERNATIONAL HYDROGRAPHIC BUREAU, *Hydrographic Dictionary*, 3rd ed. (1970), contains useful information; and *International Hydrographic Bulletin* (monthly) and *International Hydrographic Review* (semiannual), published by the same organization, provide data on current research and developments.

Marketing and Merchandising

Marketing is a process whose principal function is to promote and facilitate exchange. Through marketing, individuals and groups obtain what they need and want by exchanging products and services with other parties. Such a process can occur only when there are at least two parties, each of whom has something to offer. In addition, exchange cannot occur unless the parties are able to communicate about and to deliver what they offer. Marketing is not a coercive process: all parties must be free to accept or reject what others are offering. So defined, marketing is distinguished from other modes of obtaining desired goods, such as through self-production, begging, theft, or force.

Marketing is not confined to any particular type of economy, because goods must be exchanged and therefore marketed in all economies and societies except perhaps in the most primitive. Furthermore, marketing is not a function that is limited to profit-oriented business; even such institutions as hospitals, schools, and museums engage in some forms of marketing. Within the broad scope of marketing, merchandising is concerned more specifically with promoting the sale of goods and services to consumers (*i.e.*, retailing) and hence is more characteristic of free-market economies.

Based on these criteria, marketing can take a variety of forms: it can be a set of functions, a department within an organization, a managerial process, a managerial philosophy, and a social process.

For coverage of related topics in the *Macropædia* and *Micropædia*, see the *Propædia*, sections 532 and 533, and the *Index*.

This article is divided into the following sections:

The evolving discipline of marketing

The marketing discipline had its origins in the early 20th century as an offspring of economics. Economic science had neglected the role of middlemen and the role of functions other than price in the determination of demand levels and characteristics. Early marketing economists examined agricultural and industrial markets and described them in greater detail than the classical economists. This examination resulted in the development of three approaches to the analysis of marketing activity: the commodity, the institution, and the function.

Commodity analysis studies the ways in which a product or product group is brought to market. A commodity analysis of milk, for example, traces the ways in which milk is collected at individual dairy farms, transported to and processed at local dairy cooperatives, and shipped to grocers and supermarkets for consumer purchase. Institutional analysis describes the types of businesses that play a prevalent role in marketing, such as wholesale or retail institutions. For instance, an institutional analysis of clothing wholesalers examines the ongoing concerns that wholesalers face in order to ensure both the correct supply for their customers and the appropriate inventory and shipping capabilities. Finally, a functional analysis examines the general tasks that marketing performs. For example, any marketing effort must ensure that the product is transported from the supplier to the customer. In some industries, this transportation function may be handled by a truck, while in others it may be done by mail, facsimile, television signal, or airline. All these institutions perform the same function.

Rise of marketing

As the study of marketing became more prevalent throughout the 20th century, large companies—particularly mass consumer manufacturers—began to recognize the importance of market research, better product design, effective distribution, and sustained communication with consumers in the success of their brands. Marketing concepts and techniques later moved into the industrial-goods sector and subsequently into the services sector. It soon became apparent that organizations and individuals market not only goods and services but also ideas (so-

cial marketing), places (location marketing), personalities (celebrity marketing), events (event marketing), and even the organizations themselves (public relations).

Roles of marketing

As marketing developed, it took a variety of forms. It was noted above that marketing can be viewed as a set of functions in the sense that certain activities are traditionally associated with the exchange process. A common but incorrect view is that selling and advertising are the only marketing activities. Yet, in addition to promotion, marketing includes a much broader set of functions, including product development, packaging, pricing, distribution, and customer service.

Many organizations and businesses assign responsibility for these marketing functions to a specific group of individuals within the organization. In this respect, marketing is a unique and separate entity. Those who make up the marketing department may include brand and product managers, marketing researchers, sales representatives, advertising and promotion managers, pricing specialists, and customer service personnel.

As a managerial process, marketing is the way in which an organization determines its best opportunities in the marketplace, given its objectives and resources. The marketing process is divided into a strategic and a tactical phase. The strategic phase has three components—segmentation, targeting, and positioning (STP). The organization must distinguish among different groups of customers in the market (segmentation), choose which group(s) it can serve effectively (targeting), and communicate the central benefit it offers to that group (positioning). The marketing process includes designing and implementing various tactics, commonly referred to as the "marketing mix," or the "4 Ps": product, price, place (or distribution), and promotion. The marketing mix is followed by evaluating, controlling, and revising the marketing process to achieve the organization's objectives (see below the section *Marketing-mix planning*).

The managerial philosophy of marketing puts central emphasis on customer satisfaction as the means for gaining and keeping loyal customers. Marketers urge their organizations to carefully and continually gauge target customers' expectations and to consistently meet or exceed these expectations. In order to accomplish this, everyone in all areas of the organization must focus on understanding and serving customers; it will not succeed if all marketing occurs only in the marketing department. Marketing, consequently, is far too important to be done solely by the marketing department. Marketers also want their organizations to move from practicing transaction-oriented marketing, which focuses on individual exchanges, to relationship-driven marketing, which emphasizes serving the customer over the long term. Simply getting new customers and losing old ones will not help the organization achieve its objectives.

Finally, marketing is a social process that occurs in all economies, regardless of their political structure and orientation. It is the process by which a society organizes and distributes its resources to meet the material needs of its citizens. However, marketing activity is more pronounced under conditions of goods surpluses than goods shortages. When goods are in short supply, consumers are usually so desirous of goods that the exchange process does not require significant promotion or facilitation. In contrast, when there are more goods and services than consumers need or want, companies must work harder to convince customers to exchange with them.

Relation to supply and demand

The marketing process

The marketing process consists of four elements: strategic marketing analysis, marketing-mix planning, marketing implementation, and marketing control.

STRATEGIC MARKETING ANALYSIS

The aim of marketing in profit-oriented organizations is to meet needs profitably. Companies must therefore first define which needs—and whose needs—they can satisfy. For example, the personal transportation market consists of people who put different values on an automobile's cost, speed, safety, status, and styling. No single automobile can satisfy all these needs in a superior fashion; compromises have to be made. Furthermore, some individuals may wish to meet their personal transportation needs with something other than an automobile, such as a motorcycle, a bicycle, or a bus or other form of public transportation. Because of such variables, an automobile company must identify the different preference groups, or segments, of customers and decide which group(s) they can target profitably.

Segments can be divided into even smaller groups, called subsegments or niches. A niche is defined as a small target group that has special requirements. For example, a bank may specialize in serving the investment needs of not only senior citizens but also senior citizens with high incomes and perhaps even those with particular investment preferences. It is more likely that larger organizations will serve the larger market segments (mass marketing) and ignore niches. As a result, smaller companies typically emerge that are intimately familiar with a particular niche and specialize in serving its needs.

A growing number of companies are now trying to serve "segments of one." They attempt to adapt their offer and communication to each individual customer. This is understandable, for instance, with large industrial companies that have only a few major customers. For example, The Boeing Company (United States) designs its 747 planes differently for each major customer, such as United Airlines, Inc., or American Airlines, Inc. Serving individual customers is increasingly possible with the advent of database marketing, through which individual customer characteristics and purchase histories are retained in company information systems. Even mass-marketing companies, particularly large retailers and catalog houses, compile comprehensive data on individual customers and are able to customize their offerings and communications.

A key step in marketing strategy, known as positioning, involves creating and communicating a message that clearly establishes the company or brand in relation to competitors. Thus, Volvo Aktiebolaget (Sweden) has positioned its automobile as the "safest," and Daimler-Benz AG (Germany), manufacturer of Mercedes-Benz vehicles, has positioned its car as the best "engineered." Some products may be positioned as "outstanding" in two or more ways. However, claiming superiority along several dimensions may hurt a company's credibility because consumers will not believe that any one offering can excel in all dimensions. Furthermore, although the company may communicate a particular position, customers may perceive a different image of the company as a result of their actual experiences with the company's product or through word of mouth.

MARKETING-MIX PLANNING

Having developed a strategy, a company must then decide which tactics will be most effective in achieving strategy goals. Tactical marketing involves creating a marketing mix of four components—product, price, place, promotion—that fulfills the strategy for the targeted set of customer needs.

Product. The first marketing-mix element is the product, which refers to the offering or group of offerings that will be made available to customers. In the case of a physical product, such as a car, a company will gather information about the features and benefits desired by a target market. Before assembling a product, the marketer's role is to communicate customer desires to the engineers who design the product or service. This is in contrast to past practice, when engineers designed a product based on their own preferences, interests, or expertise and then expected marketers to find as many customers as possible to buy this product. Contemporary thinking calls for products to be designed based on customer input and not solely on engineers' ideas.

Consumer input in product development

In traditional economies, the goods produced and consumed often remain the same from one generation

to the next—including food, clothing, and housing. As economies develop, the range of products available tends to expand, and the products themselves change. In contemporary industrialized societies, products, like people, go through life cycles: birth, growth, maturity, and decline. This constant replacement of existing products with new or altered products has significant consequences for professional marketers. The development of new products involves all aspects of a business—production, finance, research and development, and even personnel administration and public relations.

Packaging and branding are also substantial components in the marketing of a product. Packaging in some instances may be as simple as customers in France carrying long loaves of unwrapped bread or small produce dealers in Italy wrapping vegetables in newspapers or placing them in customers' string bags. In most industrialized countries, however, the packaging of merchandise has become a major part of the selling effort, as marketers now specify exactly the types of packaging that will be most appealing to prospective customers. The importance of packaging in the distribution of the product has increased with the spread of self-service purchases—in wholesaling as well as in retailing. Packaging is sometimes designed to facilitate the use of the product, as with aerosol containers for room deodorants. In Europe such condiments as mustard, mayonnaise, and ketchup are often packaged in tubes. Some packages are reusable, making them attractive to customers in poorer countries where metal containers, for instance, are often highly prized.

The same general marketing approach about the product applies to the development of service offerings as well. For example, a health maintenance organization (HMO) must design a contract for its members that describes which medical procedures will be covered, how much physician choice will be available, how out-of-town medical costs will be handled, and so forth. In creating a successful service mix, the HMO must choose features that are preferred and expected by target customers, or the service will not be valued in the marketplace.

Price. The second marketing-mix element is price. Ordinarily companies determine a price by gauging the quality or performance level of the offer and then selecting a price that reflects how the market values its level of quality. However, marketers also are aware that price can send a message to a customer about the product's presumed quality level. A Mercedes-Benz vehicle is generally considered to be a high-quality automobile, and it therefore can command a high price in the marketplace. But, even if the manufacturer could price its cars competitively with economy cars, it might not do so, knowing that the lower price might communicate lower quality. On the other hand, in order to gain market share, some companies have moved to "more for the same" or "the same for less" pricing, which means offering prices that are consistently lower than those of their competitors. This kind of discount pricing has caused firms in such industries as airlines and pharmaceuticals (which used to charge a price premium based on their past brand strength and reputation) to significantly reevaluate their marketing strategies.

Place. Place, or where the product is made available, is the third element of the marketing mix and is most commonly referred to as distribution. When a product moves along its path from producer to consumer, it is said to be following a channel of distribution. For example, the channel of distribution for many food products includes food-processing plants, warehouses, wholesalers, and supermarkets. By using this channel, a food manufacturer makes its products easily accessible by ensuring that they are in stores that are frequented by those in the target market. In another example, a mutual funds organization makes its investment products available by enlisting the assistance of brokerage houses and banks, which in turn establish relationships with particular customers. However, each channel participant can handle only a certain number of products: space at supermarkets is limited, and investment brokers can keep abreast of only a limited number of mutual funds. Because of this, some marketers may decide to skip steps in the channel and instead market directly to buyers through direct mail, telemarketing, door-to-door selling, shopping via television (a growing trend in the late 20th century), or factory outlets.

Promotion. Promotion, the fourth marketing-mix element, consists of several methods of communicating with and influencing customers. The major tools are sales force, advertising, sales promotion, and public relations.

Sales representatives are the most expensive means of promotion, because they require income, expenses, and supplementary benefits. Their ability to personalize the promotion process makes salespeople most effective at selling complex goods, big-ticket items, and highly personal goods—for example, those related to religion or insurance. Salespeople are trained to make presentations, answer objections, gain commitments to purchase, and manage account growth. Some companies have successfully reduced their sales-force costs by replacing certain functions (for example, finding new customers) with less expensive methods (such as direct mail and telemarketing).

Types of advertising

Advertising includes all forms of paid, nonpersonal communication and promotion of products, services, or ideas by a specified sponsor. Advertising appears in such media as print (newspapers, magazines, billboards, flyers) or broadcast (radio, television). Print advertisements typically consist of a picture, a headline, information about the product, and occasionally a response coupon. Broadcast advertisements consist of an audio or video narrative that can range from short 15-second spots to longer segments known as infomercials, which generally last 30 or 60 minutes.

While advertising presents a reason to buy a product, sales promotion offers a short-term incentive to purchase. Sales promotions often attract brand switchers (those who are not loyal to a specific brand) who are looking primarily for low price and good value. Thus, especially in markets where brands are highly similar, sales promotions can cause a short-term increase in sales but little permanent gain in market share. Alternatively, in markets where brands are quite dissimilar, sales promotions can alter market shares more permanently. The use of promotions has risen considerably during the late 20th century. This is due to a number of factors within companies, including an increased sophistication in sales promotion techniques and greater pressure to increase sales. Several market factors also have fostered this increase, including a rise in the number of brands (especially similar ones) and a decrease in the efficiency of traditional advertising due to increasingly fractionated consumer markets.

Public relations, in contrast to advertising and sales promotion, generally involves less commercialized modes of communication. Its primary purpose is to disseminate information and opinion to groups and individuals who have an actual or potential impact on a company's ability to achieve its objectives. In addition, public relations specialists are responsible for monitoring these individuals and groups and for maintaining good relationships with them. One of their key activities is to work with news and information media to ensure appropriate coverage of the company's activities and products. Public relations specialists create publicity by arranging press conferences, contests, meetings, and other events that will draw attention to a company's products or services. Another public relations responsibility is crisis management—that is, handling situations in which public awareness of a particular issue may dramatically and negatively impact the company's ability to achieve its goals. For example, when it was discovered that some bottles of Perrier sparkling water might have been tainted by a harmful chemical, Source Perrier, SA's public relations team had to ensure that the general consuming public did not thereafter automatically associate Perrier with tainted water. Other public relations activities include lobbying, advising management about public issues, and planning community events.

Because public relations does not always seek to impact sales or profitability directly, it is sometimes seen as serving a function that is separate from marketing. However, some companies recognize that public relations can work in conjunction with other marketing activities to facilitate the exchange process directly and indirectly. These

organizations have established marketing public relations departments to directly support corporate and product promotion and image management.

(P.Ko./K.A.G./Jo.D.H.)

MARKETING IMPLEMENTATION

Companies have typically hired different agencies to help in the development of advertising, sales promotion, and publicity ideas. However, this often results in a lack of coordination between elements of the promotion mix. When components of the mix are not all in harmony, a confusing message may be sent to consumers. For example, a print advertisement for an automobile may emphasize the car's exclusivity and luxury, while a television advertisement may stress rebates and sales, clashing with this image of exclusivity. Alternatively, by integrating the marketing elements, a company can more efficiently utilize its resources. Instead of individually managing four or five different promotion processes, the company manages only one. In addition, promotion expenditures are likely to be better allocated, because differences among promotion tools become more explicit. This reasoning has led to integrated marketing communications, in which all promotional tools are considered to be part of the same effort, and each tool receives full consideration in terms of its cost and effectiveness.

MARKETING EVALUATION AND CONTROL

No marketing process, even the most carefully developed, is guaranteed to result in maximum benefit for a company. In addition, because every market is changing constantly, a strategy that is effective today may not be effective in the future. It is important to evaluate a marketing program periodically to be sure that it is achieving its objectives. There are four types of marketing control, each of which has a different purpose: annual-plan control, profitability control, efficiency control, and strategic control.

The basis of annual-plan control is managerial objectives—that is to say, specific goals, such as sales and profitability, that are established on a monthly or quarterly basis. Organizations use five tools to monitor plan performance. The first is sales analysis, in which sales goals are compared with actual sales and discrepancies are explained or accounted for. A second tool is market-share analysis, which compares a company's sales with those of its competitors. Companies can express their market share in a number of ways, by comparing their own sales to total market sales, sales within the market segment, or sales of the segment's top competitors. Third, marketing expense-to-sales analysis gauges how much a company spends to achieve its sales goals. The ratio of marketing expenses to sales is expected to fluctuate, and companies usually establish an acceptable range for this ratio. In contrast, financial analysis estimates such expenses (along with others) from a corporate perspective. This includes a comparison of profits to sales (profit margin), sales to assets (asset turnover), profits to assets (return on assets), assets to worth (financial leverage), and, finally, profits to worth (return on net worth). Finally, companies measure customer satisfaction as a means of tracking goal achievement. Analyses of this kind are generally less quantitative than those described above and may include complaint and suggestion systems, customer satisfaction surveys, and careful analysis of reasons why customers switch to a competitor's product.

Profitability control and efficiency control allow a company to closely monitor its sales, profits, and expenditures. Profitability control demonstrates the relative profit-earning capacity of a company's different products and consumer groups. Companies are frequently surprised to find that a small percentage of their products and customers contribute to a large percentage of their profits. This knowledge helps a company allocate its resources and effort.

Efficiency control involves micro-level analysis of the various elements of the marketing mix, including sales force, advertising, sales promotion, and distribution. For example, to understand its sales-force efficiency, a company may keep track of how many sales calls a representative makes each day, how long each call lasts, and how much each call costs and generates in revenue. This type of analysis highlights areas in which companies can manage their marketing efforts in a more productive and cost-effective manner.

Strategic control processes allow managers to evaluate a company's marketing program from a critical long-term perspective. This involves a detailed and objective analysis of a company's organization and its ability to maximize its strengths and market opportunities. Companies can use two types of strategic control tools. The first, which a company uses to evaluate itself, is called a marketing-effectiveness rating review. In order to rate its own marketing effectiveness, a company examines its customer philosophy, the adequacy of its marketing information, and the efficiency of its marketing operations. It will also closely evaluate the strength of its marketing strategy and the integration of its marketing tactics.

Strategic control tools

The second evaluation tool is known as a marketing audit. This is a comprehensive, systematic, independent, and periodic analysis that a company uses to examine its strengths in relation to its current and potential market(s). Such an analysis is comprehensive because it covers all aspects of the marketing climate (unlike a functional audit, which analyzes one marketing activity), looking at both macro-environment factors (demographic, economic, ecological, technological, political, and cultural) and micro- or task-environment factors (markets, customers, competitors, distributors, dealers, suppliers, facilitators, and publics). The audit includes analyses of the company's marketing strategy, marketing organization, marketing systems, and marketing productivity. It must be systematic in order to provide concrete conclusions based on these analyses. To ensure objectivity, a marketing audit is best done by a person, department, or organization that is independent of the company or marketing program. Marketing audits should be done not only when the value of a company's current marketing plan is in question; they must be done periodically in order to isolate and solve problems before they arise. (K.A.G./Jo.D.H./P.Ko.)

Customers

The elements that play a role in the marketing process can be divided into three groups: customers, distributors, and facilitators. In addition to interacting with one another, these groups must interact within a business environment that is affected by a variety of forces, including governmental, economic, and social influences.

In order to understand target customers, certain questions must be answered: Who constitutes the market segment? What do they buy and why? And how, when, and where do they buy? Knowing who constitutes the market segment is not simply a matter of knowing who uses a product. Often, individuals other than the user may participate in or influence a purchasing decision. Several individuals may play various roles in the decision-making process. For instance, in the decision to purchase an automobile for a small family business, the son may be the initiator, the daughter may be an influencer, the wife may be the decider, the purchasing manager may be the buyer, and the husband may be the user. In other words, the son may read in a magazine that businesses can save money and decrease tax liability by owning or leasing company transportation. He may therefore initiate the product search process by raising this issue at a weekly business meeting. However, the son may not be the best-qualified to gather and process information about automobiles, because the daughter worked for several years in the auto industry before joining the family business. Although the daughter's expertise and research efforts may influence the process, she may not be the key decision maker. The mother, by virtue of her position in the business and in the family, may make the final decision about which car to purchase. However, the family uncle may have good negotiation skills, and he may be the purchasing agent. Thus, he will go to different car dealerships in order to buy the chosen car at the best possible price. Finally, despite the involvement of all these individuals in the purchase process, none

of them may actually drive the car. It may be purchased so that the father may use it for his frequent sales calls. In other instances, an individual may handle more than one of these purchasing functions and may even be responsible for all of them. The key is that a marketer must recognize that different people have different influences on the purchase decision, and these factors must be taken into account in crafting a marketing strategy.

In addition to knowing to whom the marketing efforts are targeted, it is important to know which products target customers tend to purchase and why they do so. Customers do not purchase "things" as much as they purchase services or benefits to satisfy needs. For instance, a conventional oven allows users to cook and heat food. Microwave oven manufacturers recognized that this need could be fulfilled—and done so more quickly—with a technology other than conventional heating. By focusing on needs rather than on products, these companies were able to gain a significant share in the food cooking and heating market.

Marketing to customers' habits

Knowledge of when, where, and how purchases are made is also useful. A furniture store whose target customers tend to make major purchases in the spring may send its mailings at the beginning of this season. A food vendor may set up a stand near the door of a busy office complex so that employees must pass the stand on their way to lunch. And a jeweler who knows that customers prefer to pay with credit cards may ensure that all major credit cards are accepted at the store. In other cases, marketers who understand specifics about buying habits and preferences also may try to alter them. Thus, a remotely situated wholesale store may use deeply discounted prices to lure customers away from the more conveniently located shopping malls.

Customers can be divided into two categories: consumer customers, who purchase goods and services for use by themselves and by those with whom they live; and business customers, who purchase goods and services for use by the organization for which they work. Although there are a number of similarities between the purchasing approaches of each type of customer, there are important differences as well.

CONSUMER CUSTOMERS

Factors influencing consumers. Four major types of factors influence consumer buying behaviour: cultural, social, personal, and psychological. Cultural factors have the broadest influence, because they constitute a stable set of values, perceptions, preferences, and behaviours that have been learned by the consumer throughout life. For example, in Western cultures consumption is often driven by a consumer's need to express individuality, while in Eastern cultures consumers are more interested in conforming to group norms. In addition to the influence of a dominant culture, consumers may also be influenced by several subcultures. In Quebec the dominant culture is French-speaking, but one influential subculture is English-speaking. Social class is also a subcultural factor: members of any given social class tend to share similar values, interests, and behaviours.

A consumer may interact with several individuals on a daily basis, and the influence of these people constitutes the social factors that impact the buying process. Social factors include reference groups—that is, the formal or informal social groups against which consumers compare themselves. Consumers may be influenced not only by their own membership groups but also by reference groups of which they wish to be a part. Thus, a consumer who wishes to be considered a successful white-collar professional may buy a particular kind of clothing because the people in this reference group tend to wear that style. Typically, the most influential reference group is the family. In this case, family includes the people who raised the consumer (the "family of orientation") as well as the consumer's spouse and children (the "family of procreation"). Within each group, a consumer will be expected to play a specific role or set of roles dictated by the norms of the group. Roles in each group generally are tied closely to status.

Personal factors include individual characteristics that, when taken in aggregate, distinguish the individual from others of the same social group and culture. These include age, life-cycle stage, occupation, economic circumstances, and lifestyle. A consumer's personality and self-conception will also influence his or her buying behaviour.

Finally, psychological factors are the ways in which human thinking and thought patterns influence buying decisions. Consumers are influenced, for example, by their motivation to fulfill a need. In addition, the ways in which an individual acquires and retains information will affect the buying process significantly. Consumers also make their decisions based on past experiences—both positive and negative.

Consumer buying tasks. A consumer's buying task is affected significantly by the level of purchase involvement. The level of involvement describes how important the decision is to the consumer; high involvement is usually associated with purchases that are expensive, infrequent, or risky. Buying also is affected by the degree of difference between brands in the product category. The buying task can be grouped into four categories based on whether involvement is high or low and whether brand differences are great or small.

Complex buying behaviour occurs when the consumer is highly involved with the purchase and when there are significant differences between brands. This behaviour can be associated with the purchase of a new home or of an advanced computer. Such tasks are complex because the risk is high (significant financial commitment), and the large differences among brands or products require gathering a substantial amount of information prior to purchase. Marketers who wish to influence this buying task must help the consumer process the information as readily as possible. This may include informing the consumer about the product category and its important attributes, providing detailed information about product benefits, and motivating sales personnel to influence final brand choice. For instance, realtors may offer consumers a book or a video featuring photographs and descriptions of each available home. And a computer salesperson is likely to spend time in the retail store providing information to customers who have questions.

Dissonance-reducing buying behaviour occurs when the consumer is highly involved but sees little difference between brands. This is likely to be the case with the purchase of a lawn mower or a diamond ring. After making a purchase under such circumstances, a consumer is likely to experience the dissonance that comes from noticing that other brands would have been just as good, if not slightly better, in some dimensions. A consumer in such a buying situation will seek information or ideas that justify the original purchase.

There are two types of low-involvement purchases. Habitual buying behaviour occurs when involvement is low and differences between brands are small. Consumers in this case usually do not form a strong attitude toward a brand but select it because it is familiar. In these markets, promotions tend to be simple and repetitive so that the consumer can, without much effort, learn the association between a brand and a product class. Marketers may also try to make their product more involving. For instance, toothpaste was at one time purchased primarily out of habit, but Proctor and Gamble Co. introduced a brand, Crest toothpaste, that increased consumer involvement by raising awareness about the importance of good dental hygiene.

Variety-seeking buying behaviour occurs when the consumer is not involved with the purchase, yet there are significant brand differences. In this case, the cost of switching products is low, and so the consumer may, perhaps simply out of boredom, move from one brand to another. Such is often the case with frozen desserts, breakfast cereals, and soft drinks. Dominant firms in such a market situation will attempt to encourage habitual buying and will try to keep other brands from being considered by the consumer. These strategies reduce customer switching behaviour. Challenger firms, on the other hand, want consumers to switch from the market leader, so they

will offer promotions, free samples, and advertising that encourage consumers to try something new.

The consumer buying process. The purchase process is initiated when a consumer becomes aware of a need. This awareness may come from an internal source such as hunger or an external source such as marketing communications. Awareness of such a need motivates the consumer to search for information about options with which to fulfill the need. This information can come from personal sources, commercial sources, public or government sources, or the consumer's own experience. Once alternatives have been identified through these sources, consumers evaluate the options, paying particular attention to those attributes the consumer considers most important. Evaluation culminates with a purchase decision, but the buying process does not end here. In fact, marketers point out that a purchase represents the beginning, not the end, of a consumer's relationship with a company. After a purchase has been made, a satisfied consumer is more likely to purchase another company product and to say positive things about the company or its product to other potential purchasers. The opposite is true for dissatisfied consumers. Because of this fact, many companies continue to communicate with their customers after a purchase in an effort to influence post-purchase satisfaction and behaviour.

Role of marketing after the purchase

For example, a plumber may be motivated to consider buying a new set of tools because his old set of tools is getting rusty. To gather information about what kind of new tool set to buy, this plumber may examine the tools of a colleague who just bought a new set, read advertisements in plumbing trade magazines, and visit different stores to examine the sets available. The plumber then processes all the information collected, focusing perhaps on durability as one of the most important attributes. In making a particular purchase, the plumber initiates a relationship with a particular tool company. This company may try to enhance post-purchase loyalty and satisfaction by sending the plumber promotions about new tools.

BUSINESS CUSTOMERS

Business customers, also known as industrial customers, purchase products or services to use in the production of other products. Such industries include agriculture, manufacturing, construction, transportation, and communication, among others. They differ from consumer markets in several respects. Because the customers are organizations, the market tends to have fewer and larger buyers than consumer markets. This often results in closer buyer-seller relationships, because those who operate in a market must depend more significantly on one another for supply and revenue. Business customers also are more concentrated; for instance, in the United States more than half of the country's business buyers are concentrated in only seven states. Demand for business goods is derived demand, which means it is driven by a demand for consumer goods. Therefore, demand for business goods is more volatile, because variations in consumer demand can have a significant impact on business-goods demand. Business markets are also distinctive in that buyers are professional purchasers who are highly skilled in negotiating contracts and maximizing efficiency. In addition, several individuals within the business usually have direct or indirect influence on the purchasing process.

Factors influencing business customers. Although business customers are affected by the same cultural, social, personal, and psychological factors that influence consumer customers, the business arena imposes other factors that can be even more influential. First, there is the economic environment, which is characterized by such factors as primary demand, economic forecast, political and regulatory developments, and the type of competition in the market. In a highly competitive market such as airline travel, firms may be concerned about price and therefore make purchases with a focus on saving money. In markets where there is more differentiation among competitors—*e.g.*, in the hotel industry—many firms may make purchases with a focus on quality rather than on price.

Second, there are organizational factors, which include the objectives, policies, procedures, structures, and systems that characterize any particular company. Some companies are structured in such a way that purchases must pass through a complex system of checks and balances, while other companies allow purchasing managers to make more individual decisions. Interpersonal factors are more salient among business customers, because the participants in the buying process—perhaps representing several departments within a company—often have different interests, authority, and persuasiveness. Furthermore, the factors that affect an individual in the business buying process are related to the participant's role in the organization. These factors include job position, risk attitudes, and income.

The business buying process. The business buying process mirrors the consumer buying process, with a few notable exceptions. Business buying is not generally need-driven and is instead problem-driven. A business buying process is usually initiated when someone in the company sees a problem that needs to be solved or recognizes a way in which the company can increase profitability or efficiency. The ensuing process follows the same pattern as that of consumers, including information search, evaluation of alternatives, purchase decision, and post-purchase evaluation. However, in part because business purchase decisions require accountability and are often closely analyzed according to cost and efficiency, the process is more systematic than consumer buying and often involves significant documentation. Typically, a purchasing agent for a business buyer will generate documentation regarding product specifications, preferred supplier lists, requests for bids from suppliers, and performance reviews.

(K.A.G./Jo.D.H./P.Ko.)

Marketing intermediaries

Many producers do not sell products or services directly to consumers and instead use marketing intermediaries to execute an assortment of necessary functions to get the product to the final user. These intermediaries, such as middlemen (wholesalers, retailers, agents, and brokers), distributors, or financial intermediaries, typically enter into longer-term commitments with the producer and make up what is known as the marketing channel, or the channel of distribution. Manufacturers use raw materials to produce finished products, which in turn may be sent directly to the retailer, or, less often, to the consumer. However, as a general rule, finished goods flow from the manufacturer to one or more wholesalers before they reach the retailer and, finally, the consumer. Each party in the distribution channel usually acquires legal possession of goods during their physical transfer, but this is not always the case. For instance, in consignment selling, the producer retains full legal ownership even though the goods may be in the hands of the wholesaler or retailer—that is, until the merchandise reaches the final user or consumer.

Channel of distribution

Channels of distribution tend to be more direct—that is, shorter and simpler—in the less industrialized nations. There are notable exceptions, however. For instance, the Ghana Cocoa Marketing Board collects cacao beans in Ghana and licenses trading firms to process the commodity. Similar marketing processes are used in other West African nations. Because of the vast number of small-scale producers, these agents operate through middlemen who, in turn, enlist sub-buyers to find runners to transport the products from remote areas. Japan's marketing organization was, until the late 20th century, characterized by long and complex channels of distribution and a variety of wholesalers. It was possible for a product to pass through a minimum of five separate wholesalers before it reached a retailer.

Companies have a wide range of distribution channels available to them, and structuring the right channel may be one of the company's most critical marketing decisions. Businesses may sell products directly to the final customer, as Land's End, Inc., does with its mail-order goods and as is the case with most industrial capital goods. Or they may use one or more intermediaries to move their goods to the final user. The design and structure of consumer marketing channels and industrial marketing channels can be quite similar or vary widely.

The channel design is based on the level of service desired by the target consumer. There are five primary service components that facilitate the marketer's understanding of what, where, why, when, and how target customers buy certain products. The service variables are quantity or lot size (the number of units a customer purchases on any given purchase occasion), waiting time (the amount of time customers are willing to wait for receipt of goods), proximity or spatial convenience (accessibility of the product), product variety (the breadth of assortment of the product offering), and service backup (add-on services such as delivery or installation provided by the channel). It is essential for the designer of the marketing channel—typically the manufacturer—to recognize the level of each service point that the target customer desires. A single manufacturer may service several target customer groups through separate channels, and therefore each set of service outputs for these groups could vary. One group of target customers may want elevated levels of service (that is, fast delivery, high product availability, large product assortment, and installation). Their demand for such increased service translates into higher costs for the channel and higher prices for customers. However, the prosperity of discount and warehouse stores demonstrates that customers are willing to accept lower service outputs if this leads to lower prices.

Channel functions and flows. In order to deliver the optimal level of service outputs to their target consumers, manufacturers are willing to allocate some of their tasks, or marketing flows, to intermediaries. As any marketing channel moves goods from producers to consumers, the marketing intermediaries perform, or participate in, a number of marketing flows, or activities. The typical marketing flows, listed in the usual sequence in which they arise, are collection and distribution of marketing research information (information), development and dissemination of persuasive communications (promotion), agreement on terms for transfer of ownership or possession (negotiation), intentions to buy (ordering), acquisition and allocation of funds (financing), assumption of risks (risk taking), storage and movement of product (physical possession), buyers paying sellers (payment), and transfer of ownership (title).

Each of these flows must be performed by a marketing intermediary for any channel to deliver the goods to the final consumer. Thus, each producer must decide who will perform which of these functions in order to deliver the service output levels that the target consumers desire. Producers delegate these flows for a variety of reasons. First, they may lack the financial resources to carry out the intermediary activities themselves. Second, many producers can earn a superior return on their capital by investing profits back into their core business rather than into the distribution of their products. Finally, intermediaries, or middlemen, offer superior efficiency in making goods and services widely available and accessible to final users. For instance, in overseas markets it may be difficult for an exporter to establish contact with end users, and various kinds of agents must therefore be employed. Because an intermediary typically focuses on only a small handful of specialized tasks within the marketing channel, each intermediary, through specialization, experience, or scale of operation, can offer a producer greater distribution benefits.

Management of channel systems. Although middlemen can offer greater distribution economy to producers, gaining cooperation from these middlemen can be problematic. Middlemen must continuously be motivated and stimulated to perform at the highest level. In order to gain such a high level of performance, manufacturers need some sort of leverage. Researchers have distinguished five bases of power: coercive (threats if the middlemen do not comply), reward (extra benefits for compliance), legitimate (power by position—rank or contract), expert (special knowledge), and referent (manufacturer is highly respected by the middlemen).

As new institutions emerge or products enter different life-cycle phases, distribution channels change and evolve. With these types of changes, no matter how well the channel is designed and managed, conflict is inevitable. Often this conflict develops because the interests of the independent businesses do not coincide. For example, franchisers, because they receive a percentage of sales, typically want their franchisees to maximize sales, while the franchisees want to maximize their profits, not sales. The conflict that arises may be vertical, horizontal, or multichannel in nature. When General Motors Corporation comes into conflict with its dealers, this is a vertical channel conflict. Horizontal channel conflict arises when a franchisee in a neighbouring town feels a fellow franchisee has infringed on its territory. Finally, multichannel conflict occurs when a manufacturer has established two or more channels that compete against each other in selling to the same market. For example, a major tire manufacturer may begin selling its tires through mass merchandisers, much to the dismay of its independent tire dealers.

Conflicting interests in the marketing channel

Merchandise distributors

WHOLESALERS

Wholesaling includes all activities required to sell goods or services to other firms, either for resale or for business use, usually in bulk quantities and at lower-than-retail prices. Wholesalers, also called distributors, are independent merchants operating any number of wholesale establishments. Wholesalers are typically classified into one of three groups: merchant wholesalers, brokers and agents, and manufacturers' and retailers' branches and offices.

Merchant wholesalers. Merchant wholesalers, also known as jobbers, distributors, or supply houses, are independently owned and operated organizations that acquire title ownership of the goods that they handle. There are two types of merchant wholesalers: full-service and limited-service.

Full-service wholesalers usually handle larger sales volumes; they may perform a broad range of services for their customers, such as stocking inventories, operating warehouses, supplying credit, employing salespeople to assist customers, and delivering goods to customers. General-line wholesalers carry a wide variety of merchandise, such as groceries; specialty wholesalers, on the other hand, deal with a narrow line of goods, such as coffee and tea, cigarettes, or seafood.

Limited-service wholesalers, who offer fewer services to their customers and suppliers, emerged in order to reduce the costs of service. There are several types of limited-service wholesalers. Cash-and-carry wholesalers usually handle a limited line of fast-moving merchandise, selling to smaller retailers on a cash-only basis and not delivering goods. Truck wholesalers or jobbers sell and deliver directly from their vehicles, often for cash. They carry a limited line of semiperishables such as milk, bread, and snack foods. Drop shippers do not carry inventory or handle the merchandise. Operating primarily in bulk industries such as lumber, coal, and heavy equipment, they take orders but have manufacturers ship merchandise directly to final consumers. Rack jobbers, who handle nonfood lines such as housewares or personal goods, primarily serve drug and grocery retailers. Rack jobbers typically perform such functions as delivery, shelving, inventory stacking, and financing. Producers' cooperatives—owned by their members, who are farmers—assemble farm produce to be sold in local markets and share profits at the end of the year.

In less-developed countries, wholesalers are often the sole or primary means of trade; they are the main elements in the distribution systems of many countries in Latin America, East Asia, and Africa. In such countries the business activities of wholesalers may expand to include manufacturing and retailing, or they may branch out into nondistributive ventures such as real estate, finance, or transportation. Until the late 1950s, Japan was dominated by wholesaling. Even relatively large manufacturers and retailers relied principally on wholesalers as their intermediaries. However, in the late 20th century, Japanese wholesalers have declined in importance. Even in the most highly industrialized nations, however, wholesalers remain essential to the operations of significant numbers of small retailers.

Brokers and agents. Manufacturers may use brokers and agents, who do not take title possession of the goods, in marketing their products. Brokers and agents typically perform only a few of the marketing flows, and their main function is to ease buying and selling—that is, to bring buyers and sellers together and negotiate between them. Brokers, most commonly found in the food, real estate, and insurance industries, may represent either a buyer or a seller and are paid by the party who hires them. Brokers often can represent several manufacturers of noncompeting products on a commission basis. They do not carry inventory or assume risk.

Unlike merchant wholesalers, agent middlemen do not take legal ownership of the goods they sell; nor do they generally take physical possession of them. The three principal types of agent middlemen are manufacturers' agents, selling agents, and purchasing agents. Manufacturers' agents, who represent two or more manufacturers' complementary lines on a continuous basis, are usually compensated by commission. As a rule, they carry only part of a manufacturer's output, perhaps in areas where the manufacturer cannot maintain full-time salespeople. Many manufacturers' agents are businesses of only a few employees and are most commonly found in the furniture, electric, and apparel industries. Sales agents are given contractual authority to sell all of a manufacturer's output and generally have considerable autonomy to set prices, terms, and conditions of sale. Sometimes they perform the duties of a manufacturer's marketing department, although they work on a commission basis. Sales agents often provide market feedback and product information to the manufacturers and play an important role in product development. They are found in such product areas as chemicals, metals, and industrial machinery and equipment. Purchasing agents, who routinely have long-term relationships with buyers, typically receive, inspect, store, and ship goods to their buyers.

Manufacturers' agents

Manufacturers' and retailers' branches and offices. Wholesaling operations conducted by the sellers or buyers themselves rather than by independent wholesalers comprise the third major type of wholesaling. Manufacturers may engage in wholesaling through their sales branches and offices. This allows manufacturers to improve the inventory control, selling, and promotion flows. Numerous retailers also establish purchasing offices in major market centres such as Chicago and New York City that play a role similar to that of brokers and agents. The major difference is that they are part of the buyer's own organization.

RETAILERS

Retailing, the merchandising aspect of marketing, includes all activities required to sell directly to consumers for their personal, nonbusiness use. The firm that performs this consumer selling—whether it is a manufacturer, wholesaler, or retailer—is engaged in retailing. Retailing can take many forms: goods or services may be sold in person, by mail, telephone, television, or computer, or even through vending machines. These products can be sold on the street, in a store, or in the consumer's home. However, businesses that are classified as retailers secure the vast majority of their sales volume from store-based retailing.

The history of retailing. For centuries most merchandise was sold in marketplaces or by peddlers. In many countries, hawkers still sell their wares while traveling from one village to the next. Marketplaces are still the primary form of retail selling in these villages. This was also true in Europe until the Renaissance, when market stalls in certain localities became permanent and eventually grew into stores and business districts.

Retail chains are known to have existed in China several centuries before the Christian era and in some European cities in the 16th and 17th centuries. However, the birth of the modern chain store can be traced to 1859, with the inauguration of what is now the Great Atlantic & Pacific Tea Company, Inc. (A&P), in New York City. During the 15th and 16th centuries the Fugger family of Germany was the first to carry out mercantile operations of a chain-store variety. In 1670 the Hudson's Bay Company chartered its chain of outposts in Canada.

Department stores also were seen in Europe and Asia as early as the 17th century. The famous Bon Marché in Paris grew from a large specialty store into a full-fledged department store in the mid-1800s. By the middle of the 20th century, department stores existed in major U.S. cities, although small independent merchants still constitute the majority of retailers.

Shopping malls, a late 20th-century development in retail practices, were created to provide for a consumer's every need in a single, self-contained shopping area. Although they were first created for the convenience of suburban populations, they can now also be found on main city thoroughfares. A large branch of a well-known retail chain usually serves as a mall's retail flagship, which is the primary attraction for customers. In fact, few malls can be financed and built without a flagship establishment already in place.

Other mall proprietors have used recreation and entertainment to attract customers. Movie theatres, holiday displays, and live musical performances are often found in shopping malls. In Asian countries, malls also have been known to house swimming pools, arcades, and amusement parks. Hong Kong's City Plaza shopping mall includes one of the territory's two ice rinks. Some malls, such as the Mall of America in Bloomington, Minn., U.S., may offer exhibitions, sideshows, and other diversions.

Although there is a great variety of retail enterprises, with new types constantly emerging, they can be classified into three main types: store retailers, nonstore retailers, and retail organizations.

Store retailers. Several different types of stores participate in retail merchandising. The following is a brief description of the most important store retailers.

Specialty stores. A specialty store carries a deep assortment within a narrow line of goods. Furniture stores, florists, sporting-goods stores, and bookstores are all specialty stores. Stores such as Athlete's Foot (sports shoes only) and Tall Men (clothing for tall men) are considered superspecialty stores because they carry a very narrow product line.

Department stores. Department stores carry a wider variety of merchandise than most stores but offer these items in separate departments within the store. These departments usually include home furnishings and household goods, as well as clothing, which may be divided into departments according to gender and age. Department stores in western Europe and Asia also have large food departments, such as the renowned food court at Harrods in the United Kingdom. Departments within each store are usually operated as separate entities, each with its own buyers, promotions, and service personnel. Some departments, such as restaurants and beauty parlours, are leased to external providers.

Importance of department stores

Department stores generally account for less than 10 percent of a country's total retail sales, but they draw large numbers of customers in urban areas. The most influential of the department stores may even be trendsetters in various fields, such as fashion. Department stores such as Sears, Roebuck and Company have also spawned chain organizations. Others may do this through mergers or by opening branch units within a region or by expanding to other countries.

Supermarkets. Supermarkets are characterized by large facilities (15,000 to 25,000 square feet [1,394 to 2,323 square metres] with more than 12,000 items), low profit margins (earning about 1 percent operating profit on sales), high volume, and operations that serve the consumer's total needs for items such as food (groceries, meats, produce, dairy products, baked goods) and household sundries. They are organized according to product departments and operate primarily on a self-service basis. Supermarkets also may sell wines and other alcoholic beverages (depending on local licensing laws) and clothing.

The first true supermarket was opened in the United States by Michael Cullin in 1930. His King Kullen chain of large-volume food stores was so successful that it encouraged the major food-store chains to convert their specialty stores into supermarkets. When compared with the conventional independent grocer, supermarkets generally

offered greater variety and convenience and often better prices as well. Consequently, in the two decades after World War II, the supermarket drove many small food retailers out of business, not only in the United States but throughout the world. In France, for example, the number of larger food stores grew from about 50 in 1960 to 4,700 in 1982, while the number of small food retailers fell from 130,000 to 60,000.

Convenience stores. Located primarily near residential areas, convenience stores are relatively small outlets that are open long hours and carry a limited line of high-turnover convenience products at high prices. Although many have added food services, consumers use them mainly for "fill-in" purchases, such as bread, milk, or miscellaneous goods.

Superstores. Superstores, hypermarkets, and combination stores are unique retail merchandisers. With facilities averaging 35,000 square feet, superstores meet many of the consumer's needs for food and nonfood items by housing a full-service grocery store as well as such services as dry cleaning, laundry, shoe repair, and cafeterias. Combination stores typically combine a grocery store and a drug store in one facility, utilizing approximately 55,000 square feet of selling space. Hypermarkets combine supermarket, discount, and warehousing retailing principles by going beyond routinely purchased goods to include furniture, clothing, appliances, and other items. Ranging in size from 80,000 to 220,000 square feet, hypermarkets display products in bulk quantities that require minimum handling by store personnel.

Discount stores. Selling merchandise below the manufacturer's list price is known as discounting. The discount store has become an increasingly popular means of retailing. Following World War II, a number of retail establishments in the United States began to pursue a high-volume, low-profit strategy designed to attract price-conscious consumers. A key strategy for keeping operating costs (and therefore prices) low was to locate in low-rent shopping districts and to offer minimal service assistance. This no-frills approach was used at first only with hard goods, or consumer durables, such as electrical household appliances, but it has since been shown to be successful with soft goods, such as clothing. This practice has been adopted for a wide variety of products, so that discount stores have essentially become department stores with reduced prices and fewer services. In the late 20th century, discount stores began to operate outlet malls. These groups of discount stores are usually located some distance away from major metropolitan areas and have facilities that make them indistinguishable from standard shopping malls. As they gained popularity, many discount stores improved their facilities and appearances, added new lines and services, and opened suburban branches. Coupled with attempts by traditional department stores to reduce prices in order to compete with discounters, the distinction between many department and discount stores has become blurred. Specialty discount operations have grown significantly in electronics, sporting goods, and books.

Off-price retailers. Off-price retailers offer a different approach to discount retailing. As discount houses tried to increase services and offerings in order to upgrade, off-price retailers invaded this low-price, high-volume sector. Off-price retailers purchase at below-wholesale prices and charge less than retail prices. This practice is quite different from that of ordinary discounters, who buy at the market wholesale price and simply accept lower margins by pricing their products below retail costs. Off-price retailers carry a constantly changing collection of overruns, irregulars, and leftover goods and have made their biggest forays in the clothing, footwear, and accessories industries. The three primary examples of off-price retailers are factory outlets, independent carriers, and warehouse clubs. Stocking manufacturers' surplus, discontinued, or irregular products, factory outlets are owned and operated by the manufacturer. Independent off-price retailers carry a rapidly changing collection of higher-quality merchandise and are typically owned and operated by entrepreneurs or divisions of larger retail companies. Warehouse (or wholesale) clubs operate out of enormous, low-cost facilities and charge patrons an annual membership fee. They sell a limited selection of brand-name grocery items, appliances, clothing, and miscellaneous items at a deep discount. These warehouse stores, such as Wal-Mart-owned Sam's, Price Club, and Costco (in the United States), maintain low costs because they buy products at huge quantity discounts, use less labour in stocking, and typically do not make home deliveries or accept credit cards.

Nonstore retailers. Some retailers do not operate stores, and these nonstore businesses have grown much faster than store retailers. With some market observers predicting that by the year 2000 nonstore retailing will handle 30 percent of all general merchandise sold, nonstore channels may become a powerful force in the retailing industry. The major types of nonstore retailing are direct selling, direct marketing, and automatic vending.

Growth of nonstore enterprise

Direct selling. This form of retailing originated several centuries ago and has mushroomed into a $9 billion industry consisting of about 600 companies selling door-to-door, office-to-office, or at private-home sales meetings. The forerunners in the direct-selling industry include The Fuller Brush Company (brushes, brooms, etc.), Electrolux (vacuum cleaners), and Avon (cosmetics). In addition, Tupperware pioneered the home-sales approach, in which friends and neighbours gather in a home where Tupperware products are demonstrated and sold. Network marketing, a direct-selling approach similar to home sales, is also gaining prevalence in markets worldwide. Network marketing companies such as Amway and Shaklee reward their distributors not only for selling products but also for recruiting others to become distributors.

Direct marketing. Direct marketing is direct contact between a seller (manufacturer or retailer) and a consumer. Generally speaking, a seller can measure response to an offer because of its direct addressability. Although direct marketing gained wide popularity as a marketing strategy only in the late 20th century, it has been successfully utilized for more than a hundred years. The world's largest catalog houses—Sears, Roebuck and Company and Montgomery Ward & Co.—began as direct marketers in the late 1880s, selling their products solely by mail order. A century later, however, both companies were conducting most of their business in retail stores. Some department stores and specialty stores may supplement their store operations with direct-marketing transactions by mail or telephone. Mail-order firms grew rapidly in the 1950s and '60s in continental Europe, Great Britain, and certain other highly industrialized nations. Modern direct marketing is generally supported by advanced database technologies that track each customer's purchase behaviour. These technologies are used by established retail firms, such as Quelle and Neckermann in Germany, and are the foundation of mail-order businesses such as J. Crew, The Sharper Image, and L.L. Bean (all in the United States). Direct marketing is not a worldwide business phenomenon, however, because mail-order operations require infrastructure elements that are still lacking in many countries, such as efficient transportation networks and secure methods for transmitting payments.

Direct marketing has expanded from its early forms, among them direct mail and catalog mailings, to include such vehicles as telemarketing, direct-response radio and television, and electronic shopping. Unlike many other forms of promotion, a direct-marketing campaign is quantitatively measurable.

Automatic vending. Automatic vending is a unique area in nonstore merchandising because the variety of merchandise offered through automatic vending machines continues to grow. Initially, impulse goods with high convenience value such as cigarettes, soft drinks, candy, newspapers, and hot beverages were offered. However, a wide array of products such as hosiery, cosmetics, food snacks, postage stamps, paperback books, record albums, camera film, and even fishing worms are becoming available through machines.

Vending-machine operations are usually offered in sites owned by other businesses, institutions, and transportation agencies. They can be found in offices, gasoline stations, large retail stores, hotels, restaurants, and many other lo-

cales. In Japan, vending machines now dispense frozen beef, fresh flowers, whiskey, jewelry, and even names of prospective dating partners. In Sweden, vending machines have developed as a supplementary channel to retail stores, where hours of business are restricted by law. High costs of manufacturing, installation, and operation have somewhat limited the expansion of vending-machine retailing. In addition, consumers typically pay a high premium for vended merchandise.

Retail organizations. While merchants can sell their wares through a store or nonstore retailing format, retail organizations can also structure themselves in several different ways. The major types of retail organizations are corporate chains, voluntary chains and retailer cooperatives, consumer cooperatives, franchise organizations, and merchandising conglomerates.

Corporate chains. Two or more outlets that have common ownership and control, centralized buying and merchandising operations, and similar lines of merchandise are considered corporate chain stores. Corporate chain stores appear to be strongest in the food, drug, shoe, variety, and women's clothing industries. Managed chain stores have a number of advantages over independently managed stores. Because managed chains buy large volumes of products, suppliers are willing to offer cost advantages that are not usually available to other stores. These savings can be passed on to consumers in the form of lower prices and better sales. In addition, because managed chains operate on such a large scale, they can hire more specialized and experienced personnel, who may be better able to take full advantage of purchasing and promotion opportunities. Chain stores also have the opportunity to take advantage of economies of scale in the areas of advertising, store design, and inventory control. However, a corporate chain may have disadvantages as well. Its size and bureaucracy often weaken staff members' personal interest, drive, creativity, and customer-service motivation.

Voluntary chains and retailer cooperatives. These are associations of independent retailers, unlike corporate chains. Wholesaler-sponsored voluntary chains of retailers who engage in bulk buying and collective merchandising are prevalent in many countries. True Value hardware stores represent this type of arrangement in the United States. In western Europe in the 1980s there were several large wholesaler-sponsored chains of retailers, each including more than 15,000 stores. These retail stores were located across 18 countries, each store using the same name and, as a rule, offering the same brands of products but remaining an independent enterprise. Wholesaler-sponsored chains offer the same types of services for their clients as do the financially integrated retail chains. Retailer cooperatives, such as ACE hardware stores, are grouped as independent retailers who establish a central buying organization and conduct joint promotion efforts.

Consumer-owned businesses

Consumer cooperatives. Consumer cooperatives, or co-ops, are retail outlets that are owned and operated by consumers for their mutual benefit. The first consumer cooperative store was established in Rochdale, Eng., in 1844, and most co-ops are modeled after the same, original principles. They are based on open consumer membership, equal voting among members, limited customer services, and shared profits among members in the form of rebates generally related to the amounts of their purchases. Consumer cooperatives have gained widespread popularity throughout western and northern Europe, particularly in Denmark, Finland, Iceland, Norway, Sweden, and Great Britain. Co-ops typically emerge because community residents believe that local retailers' prices are too high or service is substandard.

Franchise organizations. Franchise arrangements are characterized by a contractual relationship between a franchiser (a manufacturer, wholesaler, or service organization) and franchisees (independent entrepreneurs who purchase the right to own and operate any number of units in the franchise systems). Typified by a unique product, service, business method, trade name, or patent, franchises have been prominent in many industries, including fast foods, video stores, health and fitness centres, hair salons, auto rentals, motels, and travel agencies. McDonald's Corporation is a prominent example of a franchise retail organization, with franchises all over the world.

Merchandising conglomerates. Merchandising conglomerates combine several diversified retailing lines and forms under central ownership, as well as integrate distribution and management of functions. Merchandising conglomerates are relatively free-form corporations. In the United States, Woolworth Corporation is considered a merchandising conglomerate because it operates Kinney shoe stores, Herald Square Stationers, Frame Scene, and Kids Mart. (Jo.D.H./K.A.G./P.Ko.)

Marketing facilitators

Because marketing functions require significant expertise, it is often both efficient and effective for an organization to use the assistance of independent marketing facilitators. These are organizations and consultants whose sole or primary responsibility is to handle marketing functions. In many larger companies, all or some of these functions are performed internally. However, this is not necessary or justifiable in most companies, which usually require only part-time or periodic assistance from marketing facilitators. Also, most companies cannot afford to support the salaries and operating expenses required to maintain marketing facilitators as a permanent part of their staff. Furthermore, independent marketing contractors can be more effective than an internal department because nonemployee facilitators can have broader expertise and more objective perspectives. In addition, independent contractors often are more motivated to perform at high standards, because competition in the facilitator market is usually aggressive, and poor performance could mean lost business.

There are four major types of marketing facilitators: advertising agencies, market research firms, transportation firms, and warehousing firms.

ADVERTISING AGENCIES

Advertising agencies are responsible for initiating, managing, and implementing paid marketing communications. In addition, some agencies have diversified into other types of marketing communications, including public relations, sales promotion, interactive media, and direct marketing. Agencies typically consist of four departments: account management, a creative division, a research group, and a media planning department. Those in account management act as liaisons between the client and the agency, ensuring that client needs are communicated to the agency and that agency recommendations are clearly understood by the client. Account managers also manage the flow of work within the agency, making sure that projects proceed according to schedule. The creative department is where advertisements are conceived, developed, and produced. Artists, writers, and producers work together to craft a message that meets agency and client objectives. In this department, slogans, jingles, and logos are developed. The research department gathers and processes data about the target market and consumers. This information provides a foundation for the work of the creative department and account management. Media planning personnel specialize in selecting and placing advertisements in print and broadcast media.

Creating the advertising message

MARKET RESEARCH FIRMS

Market research firms gather and analyze data about customers, competitors, distributors, and other actors and forces in the marketplace. A large portion of the work performed by most market research firms is commissioned by specific companies for particular purposes. However, some firms also routinely collect a wide spectrum of data and then attempt to sell some or all of it to companies that may benefit from such information. For example, the A.C. Nielsen Co. in the United States specializes in supplying marketing data about consumer television viewing habits, and Information Resources, Inc. (IRI), has an extensive database regarding consumer supermarket purchases.

Marketing research may be quantitative, qualitative, or a combination of both. Quantitative research is numerically

oriented, requires significant attention to the measurement of market phenomena, and often involves statistical analysis. For example, when a restaurant asks its customers to rate different aspects of its service on a scale from 1 (good) to 10 (poor), this provides quantitative information that may be analyzed statistically. Qualitative research focuses on descriptive words and symbols and usually involves observing consumers in a marketing setting or questioning them about their product or service consumption experiences. For example, a marketing researcher may stop a consumer who has purchased a particular type of detergent and ask him why that detergent was chosen. Qualitative and quantitative research each provides different insights into consumer behaviour, and research results are ordinarily more useful when the two methods are combined.

Market research can be thought of as the application of scientific method to the solution of marketing problems. It involves studying people as buyers, sellers, and consumers, examining their attitudes, preferences, habits, and purchasing power. Market research is also concerned with the channels of distribution, with promotion and pricing, and with the design of the products and services to be marketed.

TRANSPORTATION FIRMS

As a product moves from producer to consumer, it must often travel long distances. Many products consumed in the United States have been manufactured in another area of the world, such as Asia or Mexico. In addition, if the channel of distribution includes several firms, the product must be moved a number of times before it becomes accessible to consumers. A basic home appliance begins as a raw material (iron ore at a steel mill, for example) that is transported from a processing plant to a manufacturing facility.

Transportation firms assist marketers in moving products from one point in a channel to the next. An important matter of negotiation between companies working together in a channel is whether the sender or receiver of goods is responsible for transportation. Movement of products usually involves significant cost, risk, and time management. Thus, when firms consider a transportation option, they carefully weigh its dependability and price, frequency of operation, and accessibility. A firm that has its own transportation capabilities is known as a private carrier. There are also contract carriers, which are independent transportation firms that can be hired by companies on a long- or short-term basis. A common carrier provides services to any and all companies between predetermined points on a scheduled basis. The U.S. Postal Service is a common carrier, as are Federal Express and the Amtrak railway system.

WAREHOUSING FIRMS

Because products are not usually sold or shipped as soon as they are produced or delivered, firms require storage facilities. Two types of warehouses meet this need: storage warehouses hold goods for longer periods of time, and distribution warehouses serve as way stations for goods as they pass from one location to the next. Like the other marketing functions, warehouses can be wholly owned by firms, or space can be rented as needed. Although companies have more control over wholly owned facilities, warehouses of this sort can tie up capital and firm resources. Operations within warehouses usually require inspecting goods. tracking inventories, repackaging goods, shipping, and invoicing. (K.A.G./P.Ko./Jo.D.H.)

Marketing in different sectors

Although the basic principles of marketing apply to all industries, the ways in which these principles are best applied can differ considerably based on the kind of product or service sold, the kind of buying behaviour associated with the purchase, and the sector (government, consumer goods, services, etc.).

The government market. This market consists of federal, state, and local governmental units that purchase or rent goods to fulfill their functions and responsibilities for the public. Government agencies purchase a wide range of products and services, including helicopters, paintings, office furniture, clothing, alcohol, and fuel. Most of the agencies manage a significant portion of their own purchasing.

Civilian and military markets

One prominent sector of the government market is the federal civilian buying establishment. In the United States this establishment consists of six categories: departments (*e.g.,* the Department of Commerce), administration (*e.g.,* the General Services Administration), agencies (*e.g.,* the Federal Aviation Administration), boards (*e.g.,* the Railroad Retirement Board), commissions (*e.g.,* the Federal Communications Commission), and the executive office (*e.g.,* the Office of Management and Budget). In addition there are several miscellaneous civilian buying establishments, such as, for example, the Tennessee Valley Authority.

Another governmental purchasing sector is the federal military buying establishment, represented in the United States by the Department of Defense, which purchases primarily through the Defense Supply Agency and the army, navy, and air force. The Defense Supply Agency operates six supply centres, which specialize in construction, electronics, fuel, personnel support, and industrial and general supplies.

Government purchasing procedures fall into two categories: the open bid and the negotiated contract. Under open-bid buying, the government disseminates very specific information about the products and services required and requests bids from suppliers. Contracts generally are awarded to the lowest bidder. In negotiated-contract buying, a government agency negotiates directly with one or more companies regarding a specific project or supply need. In most cases, contracts are negotiated for complex projects that involve major research-and-development costs and in matters where there is little effective competition.

Consumer-goods marketing. Consumer goods can be classified according to consumer shopping habits. Convenience goods are those that the customer purchases frequently, immediately, and with minimum effort. Tobacco products, soaps, and newspapers are all considered convenience goods, as are common staples like ketchup or pasta. Convenience-goods purchasing is usually based on habitual behaviour, where the consumer will routinely purchase a particular product. Some convenience goods, however, may be purchased impulsively, involving no habit, planning, or search effort. These goods, usually displayed near the cash register in a store in order to encourage quick choice and purchase, include candy, razors, and batteries. A slightly different type of convenience product is the emergency good, which is purchased when there is an urgent need. Such goods include umbrellas and snow shovels, and these are usually distributed at a wide variety of outlets so that they will be readily available when necessary.

A second type of product is the shopping good, which usually requires a more involved selection process than convenience goods. A consumer usually compares a variety of attributes, including suitability, quality, price, and style. Homogeneous shopping goods are those that are similar in quality but different enough in other attributes (such as price, brand image, or style) to justify a search process. These products might include automobile tires or a stereo or television system. Homogeneous shopping goods are often sold strongly on price.

With heterogeneous shopping goods, product features become more important to the consumer than price. Such is often the case with the purchase of major appliances, clothing, furniture, and high-tech equipment. In this situation, the item purchased must be a certain size or colour and must perform very specific functions that cannot be fulfilled by all items offered by every supplier. With goods of this sort, the seller has to carry a wide assortment to satisfy individual tastes and must have well-trained salespeople to provide both information and advice to consumers.

Specialty goods have particularly unique characteristics and brand identifications for which a significant group of buyers is willing to make a special purchasing effort. Examples include specific brands of fancy products, lux-

ury cars, professional photographic equipment, and high-fashion clothing. For instance, consumers who favour merchandise produced by a certain shoe manufacturer or furniture maker will, if necessary, travel considerable distances in order to purchase that particular brand. In specialty-goods markets, sellers do not encourage comparisons between options; buyers invest time to reach dealers carrying the product desired, and these dealers therefore do not necessarily need to be conveniently located.

Finally, an unsought good is one that a consumer does not know about—or knows about but does not normally think of buying. New products, such as new frozen-food concepts or new communications equipment, are unsought until consumers learn about them through word-of-mouth influence or advertising. In addition, the need for unsought goods may not seem urgent to the consumer, and purchase is often deferred. This is frequently the case with life insurance, preventive car maintenance, and cemetery plots. Because of this, unsought goods require significant marketing efforts, and some of the more sophisticated selling techniques have been developed from the challenge to sell unsought goods.

Services marketing. A service is an act of labour or a performance that does not produce a tangible commodity and does not result in the customer's ownership of anything. Its production may or may not be tied to a physical product. Thus, there are pure services that involve no tangible product (as with psychotherapy), tangible goods with accompanying services (such as a computer software package with free software support), and hybrid product-services that consist of parts of each (for instance, restaurants are usually patronized for both their food and their service).

Services can be distinguished from products because they are intangible, inseparable from the production process, variable, and perishable. Services are intangible because they can often not be seen, tasted, felt, heard, or smelled before they are purchased. A person purchasing plastic surgery cannot see the results before the purchase, and a lawyer's client cannot anticipate the outcome of a case before the lawyer's work is presented in court. To reduce the uncertainty that results from this intangibility, marketers may strive to make their service tangible by emphasizing the place, people, equipment, communications, symbols, or price of the service. For example, consider the insurance slogans "You're in good hands with Allstate" or Prudential's "Get a piece of the Rock."

Services are inseparable from their production because they are typically produced and consumed simultaneously. This is not true of physical products, which are often consumed long after the product has been manufactured, inventoried, distributed, and placed in a retail store. Inseparability is especially evident in entertainment services or professional services. In many cases, inseparability limits the production of services because they are so directly tied to the individuals who perform them. This problem can be alleviated if a service provider learns to work faster or if the service expertise can be standardized and performed by a number of individuals (as H&R Block, Inc., has done with its network of trained tax consultants throughout the United States).

Increasing service production

The variability of services comes from their significant human component. Not only do humans differ from one another, but their performance at any given time may differ from their performance at another time. The mechanics at a particular auto service garage, for example, may differ in terms of their knowledge and expertise, and each mechanic will have "good" days and "bad" days. Variability can be reduced by quality-control measures. These measures can include good selection and training of personnel and allowing customers to communicate dissatisfaction (*e.g.*, through customer suggestion and complaint systems) so that poor service can be detected and corrected.

Finally, services are perishable because they cannot be stored. Because of this, it is difficult for service providers to manage anything other than steady demand. When demand increases dramatically, service organizations face the problem of producing enough output to meet customer needs. When a large tour bus unexpectedly arrives at a restaurant, its staff must rush to meet the demand, because the food services (taking orders, making food, taking money, etc.) cannot be "warehoused" for such an occasion. To manage such instances, companies may hire part-time employees, develop efficiency routines for peak demand occasions, or ask consumers to participate in the service-delivery process. On the other hand, when demand drops off precipitously, service organizations are often burdened with a staff of service providers who are not performing. Organizations can maintain steady demand by offering differential pricing during off-peak times, anticipating off-peak hours by requiring reservations, and giving employees more flexible work shifts.

(K.A.G./Jo.D.H./P.Ko.)

Business marketing. Business marketing, sometimes called business-to-business marketing or industrial marketing, involves those marketing activities and functions that are targeted toward organizational customers. This type of marketing involves selling goods (and services) to organizations (public and private) to be used directly or indirectly in their own production or service-delivery operations. Some of the major industries that comprise the business market are construction, manufacturing, mining, transportation, public utilities, communications, and distribution. One of the key points that differentiates business from consumer marketing is the magnitude of the transactions. For example, in the mid-1990s, a Boeing 747 airliner, selling for about $155 million, could take up to four years to manufacture and deliver once the order was placed. Often, a major airline company will order several aircraft at one time, making the purchase price as high as a billion dollars.

Customers for industrial goods can be divided into three groups: user customers, original-equipment manufacturers, and resellers. User customers make use of the goods they purchase in their own businesses. An automobile manufacturer, for example, might purchase a metal-stamping press to produce parts for its vehicles. Original-equipment manufacturers incorporate the purchased goods into their final products, which are then sold to final consumers (*e.g.*, the manufacturer of television receivers buys tubes and transistors). Industrial resellers are middlemen—essentially wholesalers but in some cases retailers—who distribute goods to user customers, to original-equipment manufacturers, and to other middlemen. Industrial-goods wholesalers include mill-supply houses, steel warehouses, machine-tool dealers, paper jobbers, and chemical distributors.

Nonprofit marketing. Marketing scholars began exploring the application of marketing to nonprofit organizations in 1969. Since then, nonprofit organizations have increasingly turned to marketing for growth, funding, and prosperity.

Although it is difficult to define "nonprofit" organizations because of the existence of a number of quasi-governmental organizations, a study in the mid-1990s found more than one million private, nonprofit organizations in the United States. Some experts believe that the way to distinguish between organizations is according to their sources of funding. The three major sources are profits, government revenues (such as grants or taxes), and voluntary donations. In addition, a legally defined nonprofit organization is one that has been granted tax-exempt status by the Internal Revenue Service. However, while nonprofit groups can be defined legally, it is more helpful to focus on the specific marketing activities that need to be performed within the organization's environment. Museums, hospitals, universities, and churches are all examples of nonprofit organizations. Although many individuals may believe that nonprofit organizations have only a small impact on the economy, the operating expenditures of private nonprofit organizations now represent a significant percentage of the U.S. gross national product. In addition, many of these are substantial enterprises. For example, Girl Scout cookies, sold by Girl Scouts of America, constitute 10 percent of all cookies sold in the United States.

Social marketing. Social marketing employs marketing principles and techniques to advance a social cause, idea,

Purposes of social marketing

or behaviour. It entails the design, implementation, and control of programs aimed at increasing the acceptability of a social idea or practice that would benefit the adoptors or society. Social ideas can take the form of beliefs, attitudes, and values, such as human rights. Whether social marketers are promoting ideas or social practices, their ultimate goal is to alter behaviour. In order to accomplish this behaviour change, social marketers set measurable objectives, research their target group's needs, target their "products" to these particular "consumers," and effectively communicate their benefits. In addition, social-marketing organizations have to be constantly aware of changes in their environments and must be able to adapt to these changes.

Place marketing. Place marketing employs marketing principles and techniques to advance the appeal and viability of a place (town, city, state, region, or nation) to tourists, businesses, investors, and residents. Among the "place sellers" are economic development agencies, tourist promotion agencies, and mayors' offices. Place sellers must gain a deep understanding of how place buyers make their purchasing decisions. Place-marketing activities can be found in both the private and public sectors at the local, regional, national, and international levels. They can range from activities involving downtrodden cities trying to attract businesses to vacation spots seeking to attract tourists. In implementing these marketing activities, each locale must adapt to external shocks and forces beyond its control (intergovernmental power shifts, increasing global competition, and rapid technological change) as well as to internal forces and decline cycles. (Jo.D.H./P.Ko.)

Economic and social aspects of marketing

Sometimes criticized for its impact on personal economic and social well-being, marketing has been said to affect not only individual consumers but also society as a whole. This section briefly examines some of the criticisms raised and how governments, individuals, and marketers have addressed them.

Marketing and individual welfare. Criticisms have been leveled against marketers, claiming that some of their practices may damage individual welfare. While this may be true in certain circumstances, it is important to recognize that, if a business damages individual welfare, it cannot hope to continue in the marketplace for long. As a consequence, most unfavourable views of marketing are criticisms of poor marketing, not of strategically sound marketing practices.

Others have raised concerns about marketing by saying that it increases prices by encouraging excessive markups. Marketers recognize that consumers may be willing to pay more for a product—such as a necklace from Tiffany and Co.—simply because of the associated prestige. This not only results in greater costs for promotion and distribution, but it allows marketers to earn profit margins that may be significantly higher than industry norms. Marketers counter these concerns by pointing out that products provide not only functional benefits but symbolic ones as well. By creating a symbol of prestige and luxury, Tiffany's offers a symbolic benefit that, according to some consumers, justifies the price. In addition, brands may symbolize not only prestige but also quality and functionality, which gives consumers greater confidence when they purchase a branded product. Finally, advertising and promotions are often very cost-effective methods of informing the general public about items and services that are available in the marketplace.

A few marketers have been accused of using deceptive practices, such as misleading promotional activities or high-pressure selling. These deceptive practices have given rise to legislative and administrative remedies, including guidelines offered by the Federal Trade Commission (FTC) regarding advertising practices, automatic 30-day guarantee policies by some manufacturers, and "cooling off" periods during which a consumer may cancel any contract signed. In addition, professional marketing associations, such as the Direct Marketing Association, have promulgated a set of professional standards for their industry.

Marketing and societal welfare. Concern also has been raised that some marketing practices may encourage excessive interest in material possessions, create "false wants," or promote the purchase of nonessential goods. For example, in the United States, children's Saturday morning television programming came under fire for promoting materialistic values. The Federal Communications Commission (FCC) responded in the early 1990s by regulating the amount of commercial time per hour. In many of these cases, however, the criticisms overstate the power of marketing communications to influence individuals and portray members of the public as individuals unable to distinguish between a good decision and a bad one. In addition, such charges cast marketing as a cause of social problems when often the problems have much deeper societal roots.

Criticisms of marketing

Marketing activity also has been sometimes criticized because of its control by strong private interests and its neglect of social and public concern. While companies in the cigarette, oil, and alcohol industries may have significant influence on legislation, media, and individual behaviour, organizations that focus on environmental, health, or education concerns are not able to wield such influence and often fail to receive appropriate recognition for their efforts. While there is clearly an imbalance of power between private interests and public ones, in the late 20th century, private companies have received more praise for their marketing efforts for social causes.

(P.Ko./K.A.G./Jo.D.H.)

Marketing's contributions to individuals and society. Although some have questioned the appropriateness of the marketing philosophy in an age of environmental deterioration, resource shortages, world hunger and poverty, and neglected social services, numerous firms are commendably satisfying individual consumer demands as well as acting in the long-term interests of the consumer and society. These dual objectives of many of today's companies have led to a broadening of the "marketing concept" to become the "societal marketing concept." Generating customer satisfaction while at the same time attending to consumer and societal well-being in the long run are the core concepts of societal marketing.

In practicing societal marketing, marketers try to balance company profits, consumer satisfaction, and public interest in their marketing policies. Many companies have achieved success in adopting societal marketing. Two prominent examples are The Body Shop International PLC, based in England, and Ben & Jerry's Homemade Inc., which produces ice cream and is based in Vermont. Body Shop's cosmetics and personal hygiene products, based on natural ingredients, are sold in recycled packaging. The products are formulated without animal testing, and a percentage of profits each year is donated to animal rights groups, homeless shelters, Amnesty International, rain-forest preservation groups, and other social causes. Ben & Jerry's donates a percentage of its profits to help alleviate social and environmental problems. The company's corporate concept focuses on "caring capitalism," which involves the product as well as social and economic missions.

Marketing has had many other positive benefits for individuals and society. It has helped accelerate economic development and create new jobs. It has also contributed to technological progress and enhanced consumers' choices.

BIBLIOGRAPHY. The most widely used textbook is PHILIP KOTLER, *Marketing Management: Analysis, Planning, Implementation, and Control,* 8th ed. (1994). ROBERT BARTELS, *History of Marketing Thought,* 3rd ed. (1988), provides an overview of marketing through the years and contains an extensive bibliography. A more conceptual and theoretical treatment may be found in the work by WROE ALDERSON, *Dynamic Marketing Behavior: A Functionalist Theory of Marketing* (1965).

Various strategic and tactical aspects of marketing are explored in the following studies: STEVEN P. SCHNAARS, *Marketing Strategy: A Customer-Driven Approach* (1991); JACK TROUT and AL REIS, *Positioning: The Battle for Your Mind,* rev. ed. (1986); THOMAS T. NAGLE and REED K. HOLDEN, *The Strategy and Tactics of Pricing,* 2nd ed. (1994); GILBERT A. CHURCHILL, JR., NEIL M. FORD, and ORVILLE C. WALKER, JR., *Sales Force*

Management, 4th ed. (1993); DON E. SCHULTZ, STANLEY I. TANNENBAUM, and ROBERT F. LAUTERBORN, *Integrated Marketing Communications* (1992); MARY LOU ROBERTS and PAUL D. BERGER, *Direct Marketing Management* (1989); DAVID A. AAKER, *Strategic Market Management,* 3rd ed. (1991); GLEN L. URBAN and JOHN HAUSER, *Design and Marketing of New Products,* 2nd ed. (1993); and STAN RAPP and THOMAS L. COLLINS, *Beyond Maximarketing* (1994). The importance of marketing intermediaries is outlined by LOUIS W. STERN and ADEL I. EL-ANSARY, *Marketing Channels,* 4th ed. (1992).

THEODORE LEVITT, *The Marketing Imagination,* new, expanded ed. (1986); and REGIS MCKENNA, *Relationship Marketing: Successful Strategies for the Age of the Customer* (1991), discuss the evolving discipline of marketing.

The role of marketing research is investigated in the extended work by GILBERT A. CHURCHILL, JR., *Marketing Research: Methodological Foundations,* 5th ed. (1991). The role the consumer plays in the marketing process is examined in MICHAEL R. SOLOMON, *Consumer Behavior,* 2nd ed. (1994); and DAVID A. AAKER and GEORGE S. DAY, *Consumerism: Search for Consumer Interest,* 4th ed. (1982).

Advertising's role in the marketing process is explored in DAVID OGILVY, *Ogilvy on Advertising* (1983); JOHN LYONS, *Guts: Advertising from the Inside Out* (1987); and WILLIAM WELLS, JOHN BURNETT, and SANDRA MORIARTY, *Advertising: Principles and Practice,* 2nd ed. (1992).

Marketing in several different sectors is dealt with in the following selected works: DAVID A. AAKER and ALEXANDER L. BIEL, *Brand Equity & Advertising* (1993); DAVID A. AAKER, *Managing Brand Equity* (1991); CHRISTOPHER H. LOVELOCK, *Services Marketing,* 2nd ed. (1991), and *Managing Services: Marketing, Operations, and Human Resources,* 2nd ed. (1991); MICHAEL D. HUTT and THOMAS W. SPEH, *Business Marketing Management: A Strategic View of Industrial and Organizational Markets,* 4th ed. (1992); PHILIP KOTLER and ALAN R. ANDREASEN, *Strategic Marketing for Nonprofit Organizations,* 4th ed. (1991); PHILIP KOTLER and ROBERTA N. CLARKE, *Marketing for Healthcare Organizations* (1986); PHILIP KOTLER and EDUARDO ROBERTO, *Social Marketing: Strategies for Changing Public Behavior* (1989); PHILIP KOTLER, DONALD H. HEIDER, and IRVING REIN, *Marketing Places: Attracting Investment, Industry, and Tourism to Cities, States, and Nations* (1993); and MICHAEL R. CZINKOTA and ILKKA A. RONKAINEN, *International Marketing,* 3rd ed. (1993).

Current marketing trends are reported in a number of trade journals and newspapers, including *Marketing News* (biweekly); *Marketing Management* (quarterly); *Journal of Retailing* (quarterly); *Advertising Age* (weekly); *Business Marketing* (monthly); *Harvard Business Review* (bimonthly); *Wall Street Journal* (daily); *Business Week* (weekly); *Fortune* (biweekly); *California Management Review* (quarterly); and *Business Horizons* (bimonthly). More scholarly research journals include *Journal of Marketing Research* (quarterly); *Journal of Marketing* (quarterly); *Journal of Consumer Research* (quarterly); and *Journal of the Academy of Marketing Science* (quarterly).

Markets

Markets in the most literal and immediate sense are places in which things are bought and sold. In the modern industrial system, however, the market is not a place; it has expanded to include the whole geographical area in which sellers compete with each other for customers. Alfred Marshall, whose *Principles of Economics* (first published in 1890) was for long an authority for English-speaking economists, based his definition of the market on that of the French economist A. Cournot:

> Economists understand by the term Market, not any particular market place in which things are bought and sold, but the whole of any region in which buyers and sellers are in such free intercourse with one another that the prices of the same goods tend to equality easily and quickly.

To this Marshall added:

> The more nearly perfect a market is, the stronger is the tendency for the same price to be paid for the same thing at the same time in all parts of the market.

The concept of the market as defined above has to do primarily with more or less standardized commodities, for example, wool or automobiles. The word market is also used in contexts such as the market for real estate or for old masters; and there is the "labour market," although a contract to work for a certain wage differs from a sale of goods. There is a connecting idea in all of these various usages—namely, the interplay of supply and demand.

Most markets consist of groups of intermediaries between the first seller of a commodity and the final buyer. There are all kinds of intermediaries, from the brokers in the great produce exchanges down to the village grocer. They may be mere dealers with no equipment but a telephone, or they may provide storage and perform important services of grading, packaging, and so on. In general, the function of a market is to collect products from scattered sources and channel them to scattered outlets. From the point of view of the seller, dealers channel the demand for his product; from the point of view of the buyer, they bring supplies within his reach.

There are two main types of markets for products, in which the forces of supply and demand operate quite differently, with some overlapping and borderline cases. In the first, the producer offers his goods and takes whatever price they will command; in the second, the producer sets his price and sells as much as the market will take. In addition, along with the growth of trade in goods, there has been a proliferation of financial markets, including securities exchanges and money markets.

The article is divided into the following sections:

The market in economic doctrine and history

MARKET THEORY

The abstract nature of traditional market theory. The key to the modern concept of the market may be found in the famous observation of the 18th-century British economist Adam Smith that "The division of labour depends upon the extent of the market." He foresaw that modern industry depended for its development upon an extensive market for its products. The factory system developed out of trade in cotton textiles, when merchants, discovering an apparently insatiable worldwide market, became interested in increasing production in order to have more to sell. The factory system led to the use of power to supplement human muscle, followed in turn by the application of science to technology, which in an ever-accelerating spiral has produced the scope and complexity of modern industry.

19th-century views

The economic theory of the late 19th century, which is still influential in academic teaching, was, however, concerned with the allocation of existing resources between different uses rather than with technical progress. This theory was highly abstract. The concept of the market was most systematically worked out in a general equilibrium system developed by the French economist Léon Walras, who was strongly influenced by the theoretical physics of his time. His system of mathematical equations was ingenious, but there are two serious limitations to the mechanical analogy upon which they were based: it omitted the factor of time—the effect upon peoples' present behaviour of their expectations about the future; and it ignored the consequences for the human beings concerned of the distribution of purchasing power among them. Though economists have always admitted the abstract nature of the theory, they generally have accepted the doctrine that the free play of market forces tended to bring about full employment and an optimum allocation of resources. On this view, unemployment could only be caused by wages being too high. This doctrine was still influential in the Great Depression of the 1930s.

Modifications of the theory. The change in view that was to become known as the Keynesian Revolution was largely an escape to common sense, as opposed to abstract theory. In a private-enterprise economy, investment in industrial installations and housing construction is aimed at profitability in the future. Because investment therefore depends upon expectations, unfavourable expectations tend to fulfill themselves—when investment outlay falls off, workers become unemployed; incomes fall, purchases fall, unemployment spreads to the consumer goods industries, and receipts are reduced all the more. The operation of the market thus generates instability. The market may also generate instability in an upward direction. A high level of effective demand leads to a scarcity of labour; rising wages raise both costs of production and incomes so that there is a general tendency to inflation.

The turn toward realism

While the English economist John Maynard Keynes was attacking the concept of equilibrium in the market as a whole, the notion of equilibrium in the market for particular commodities was also being undermined. Traditional theory had conceived of a group of producers as operating in a perfect market for a single commodity; each produced only a small part of the whole supply; for each, the price was determined by the market; and each maximized its profits by selling only as much as would make marginal cost equal to price—that is to say, only so much that to produce a little more would add more to costs than it would to proceeds. Each firm worked its plant up to capacity—*i.e.*, to the point where profitability was limited by rising costs. This state of affairs, known as "perfect competition," is quite contrary to the general run of business experience, particularly in bad times when under-capacity working is prevalent. A theory of imperfect competition was invented to reconcile the traditional theory with under-capacity working but was attacked as unrealistic. The upshot was a general recognition that strict profit maximizing is impossible in conditions of uncertainty; that prices of manufactures are generally formed by adding a margin to direct costs, large enough to yield a profit at less than capacity sales; and that an increase in capacity generally has to be accompanied by a selling campaign to ensure that it will be used at a remunerative level.

Once it is recognized that competition is never perfect in reality, it becomes obvious that there is great scope for individual variations in the price policy of firms. No precise generalization is possible. The field is open for study of what actually happens, and exploration is going on. Meanwhile, however, textbook teaching often continues to seek refuge in the illusory simplicity of the traditional theory of market behaviour.

THE HISTORICAL DEVELOPMENT OF MARKETS

Economies without markets

History and anthropology provide many examples of economies based neither on markets nor on commerce. An exchange of gifts between communities with different resources, for example, may resemble trade, particularly in diversifying consumption and encouraging specialization in production, but subjectively it has a different meaning. Honour lies in giving; receiving imposes a burden. There is competition to see who can show the most generosity, not who can make the biggest gain. Another kind of noncommercial exchange was the payment of tribute, or dues, to a political authority, which then distributed what it had collected. On this basis, great, complex, and wealthy civilizations have arisen in which commerce was almost entirely unknown: the network of supply and distribution was operated through the administrative system. Herodotus remarked that the Persians had no marketplaces.

The distinguishing characteristic of commerce is that goods are offered not as a duty or for prestige or out of neighbourly kindness but in order to acquire purchasing power. It is clearly a convenience to all parties to have a single generally established currency-commodity. Once a commodity is acceptable as money, its use to store purchasing power overshadows its use for its original purpose; it ceases to be a commodity like any other and becomes the very embodiment of value.

The origin of markets. Markets as centres of commerce seem to have had three separate points of origin. The first was in rural fairs. A typical cultivator fed his family and paid the landlord and the moneylender from his chief crop. He had sidelines that provided salable products, and he had needs that he could not satisfy at home. It was then convenient for him to go to a market where many could meet to sell and buy.

The second point was in service to the landlords. Rent, essentially, was paid in grain; even when it was translated into money, sales of grain were necessary to supply the cultivator with funds to meet his dues. Payment of rent was a one-way transaction, imposed by the landlord. In turn, the landlord used the rents to maintain his warriors, clients, and artisans, and this led to the growth of towns as centres of trade and production. An urban class developed with a standard of life enabling its members to cater to each other as well as to the landlords and officials.

International markets

The third, and most influential, origin of markets was in international trade. From early times, merchant adventurers (the Phoenicians, the Arabs) risked their lives and their capital in carrying the products of one region to another. The importance of international trade for the development of the market system was precisely that it was carried on by third parties. Within a settled country, commercial dealings were restrained by considerations of rights, obligations, and proper behaviour. In medieval Europe, for example, dealings were regulated in the main by the concept of the "just price," that is, a system of valuations that assured the producers and merchants an income sufficient to maintain life at a level suited to their respective positions in society. But in trade in which the dealer is not subject to any obligation at either end, no holds are barred; purely commercial principles have free play. It was in trade (for instance, the export of English wool to the weavers of Italy) that the commercial principle undermined feudal conceptions of rights and duties. As Adam Smith observed, a great leap occurred when trade released the forces of industrial production.

Throughout history the relations between the trader and the producer have changed with the development of technique and with changes in the economic power of the parties. The 19th century was the heyday of the import–export merchant. Traders from a metropolitan country could establish themselves in a foreign centre, become experts on its needs and possibilities, and deal with a great variety of producers and customers, on a relatively small scale with each. With the growth of giant corporations, the scope of the merchant narrowed; his functions were largely taken over by the sales departments of the industrial concerns. Nowadays it is common to hold international fairs at which industrial products are displayed for inspection by customers, a grand and glorified version of the village market; the business, however, consists in placing orders rather than buying on the spot and carrying merchandise home. The function of the independent wholesaler, like that of the merchant, has declined as great retail businesses have grown to a scale whereby they can deal directly with manufacturers; but specialized exchanges for primary commodities are still important.

Markets under Socialism. Markets are essential to the free enterprise system; they grew and spread along with it. The propensity "to truck, barter, and exchange one thing for another" (in Adam Smith's words) was exalted into a principle of civilization by the doctrine of laissez-faire, which taught that the pursuit of self-interests by the individual would be to the benefit of society as a whole.

Markets in Communist-governed countries

In the Soviet Union and other Socialist countries, a different kind of economy existed and a different ideology was dominant. There were two interlocking systems in the economy of the Soviet Union: one for industry and one for agriculture; and the same pattern was followed, with variations, in the other Socialist countries. Industrially, all equipment and materials were owned by the state, and production was directed according to a central plan. In theory, payments to workers were thought of as their share of the total production of the economy; in practice, however, the system of wages was very much like that in capitalist industry except that rates as a rule were set by decree and the managers of enterprises had little scope for bargaining. Workers might move around looking for jobs, but there was no "labour market" in the capitalist sense. Materials and equipment were distributed among enterprises by the state planning offices. (Faulty planning gave rise to intermediaries who operated between enterprises, but this is not at all the same thing as the highly developed markets in materials, components, and equipment that exist under capitalism.)

Consumption goods, on the other hand, were distributed to Soviet households through a retail market. Though some Socialist idealists, regarding buying and selling as the essence of capitalism, have advocated that money should be abolished altogether, in a large community it has proved to be most convenient to provide incomes in the form of generalized purchasing power and to allow each to choose what he pleases from whatever goods are available. Classical economists usually assert that the advantage of the

retail market system is that it runs itself without excessive regulation; consumers who go shopping are in charge of their own money and need account to no one for what they do with it. Retail markets in the Soviet economy differed from those in capitalist economies in that, while in both systems the buyer is in this sense a principal, the seller in the Soviet model was an agent. Retailers and manufacturers all served as agents of the same authority—the central plan. Rather than making it their business to woo and cajole the customer, sellers threw supplies into the shops in a somewhat arbitrary way and customers would search for what they wanted.

Soviet agriculture was organized on principles quite different from those operative for manufacturing. Collective farms, though managed in an authoritarian way, were like cooperatives in which members shared in the income of their farm in respect to the "work points" each could earn. The value of a work point was affected by the prices set for the products of the farm, and these were politically, rather than only economically, determined. In the Western industrial economies, there is also a political element involved in the setting of agricultural prices; generally the problem here is to prevent excess production from driving prices too low. For the Soviets, the problem was the opposite. There, agricultural output failed to expand rapidly enough to keep pace with the requirements of the growing industrial labour force, and prices were therefore kept down so that they would not be unfavourable to the industrial sector. At the same time, individual members of the collective farms were permitted to sell the produce of their household plots on a free market. In this specific market, the peasant was as much a principal as the buyer.

In China, cooperative farms established after 1949 were much more genuinely cooperatives than were those in the Soviet Union, and trade with the cities in China is organized through a kind of Socialist wholesaling. City authorities place contracts with neighbouring farms, specifying prices, varieties, quantities, and delivery dates, and then direct the supplies to retail outlets, which are part of the Socialist economy. A similar system controls trade in manufactured consumer goods. Through the retail shops, the authorities monitor demand and guide supply as far as possible to meet it by the contracts that they place with the Socialist manufacturers. By adapting the wholesale trade to its own requirements, the Chinese economy seems to have avoided some of the difficulties that the Soviets encountered.

The kibbutzim in Israel

An example of socialism without a formal market was seen in the early days of the cooperative settlements known as kibbutzim in Israel, where cultivators shared the proceeds of their work without any distinction of individual incomes. (Because a kibbutz could trade with the surrounding market economy, its members were not confined to consuming only the produce of their own soil.) At the outset some of the kibbutzim carried the objection to private property so far that a man who gave a shirt to the laundry received back just some other shirt. But to dispense altogether with market relationships is apparently possible only in a small community in which all share a common ideal, and the austere standards of the original kibbutzim have softened somewhat with growing prosperity; but they still maintain a small-scale example of economic efficiency without commercial incentives.

Markets for primary products

COMMODITY MARKETS

The behaviour of primary commodity markets

The general run of agricultural commodities is produced under competitive conditions by relatively small-scale cultivators scattered over a large area. The final purchasers are also scattered, and centres of consumption are distant from regions of production. The dealer, therefore, since he is indispensable, is in a stronger economic position than the seller. This situation is markedly true when the producer is a peasant who lacks both commercial knowledge and finance so that he is obliged to sell as soon as his harvest comes in; it is true also, though to a lesser extent, of the capitalist plantation for which the only source of earnings is a particular specialized product. In this kind of business, both demand and supply are said to be inelastic in the short run—that is, a fall in price does not have much effect in increasing purchases and a rise in price cannot quickly increase supplies. Supplies are subject to natural variations, weather conditions, pests, and so forth; and demand varies with the level of activity in the centres of industry and with changes in tastes and technical requirements. Under a regime of unregulated competition such markets are, therefore, tormented with continual fluctuations in prices and volume of business. Though dealers may mitigate this to some extent by building up stocks when prices are low and releasing them when demand is high, such buying and selling often turns into speculation, which tends to exacerbate the fluctuations.

The behaviour of primary commodity markets is a serious matter when whole communities depend upon a single commodity for income or for employment and wages. The agricultural communities that form part of an industrial economy are therefore generally sheltered from the operation of supply and demand by government regulations of various types, price supports, or tariff protection. Though some attempts have been made to control world commodity markets, these are generally more talk than performance. Some nations, Australia for example, have been able to make enough profit from primary commodity exports to attract capital into the development of industry; but most of the so-called developing countries find their export earnings insecure and insufficient. Their spokesmen complain that the world market system operates in favour of the industrialized nations. (J.Ro.)

FUTURES MARKETS

Origins and development

From very early times, and in many lines of trade, buyers and sellers have found it advantageous to enter into contracts—termed futures contracts—calling for delivery of a commodity at a later date. Dutch whalers in the 16th century entered into forward sales contracts before sailing, partly to finance their voyage and partly to get a better price for their product. From early times, U.S. potato growers in Maine made forward sales of potatoes at planting time. The European futures markets arose out of import trade. Cotton importers in Liverpool, for example, entered forward contracts with U.S. exporters from about 1840. With the introduction of the fast transatlantic Cunard mail services, it became possible for cotton exporters in the United States to send samples to Liverpool in advance of the slow cargo ships, which carried the bulk of the cotton. Futures trading within the United States in the form of "to arrive" contracts appears to have commenced before the railroad days (1850s) in Chicago. Merchants in Chicago who bought wheat from outlying territories were not sure of the arrival time and quality of a delivery. The introduction of "to arrive" contracts enabled the sellers to get a better price for their product and buyers to avoid serious price risk.

Futures trading of this sort in grains, coffee, cotton, and oilseeds also arose in other centres such as Antwerp, Amsterdam, Bremen, Le Havre, Alexandria, and Ōsaka between the 17th and the middle of the 19th centuries. In the process of evolution, "to arrive" contracts became standardized with respect to grade and delivery period, with allowances for grade adjustment when the delivered grade happened to be different. These developments helped to enlarge the volume of trade, encouraging more trading by merchants who dealt in the physical commodity and also the entry of speculators, who were interested not in the commodity itself but in the favourable movement of its price in order to make profits. The larger volume of trading lowered the transaction costs, and by stages the trading became impersonal. The rise of the clearinghouse depersonalized the buyer-seller relations completely, giving rise to the present form of futures trading.

Economic functions of the futures contract. Commodity futures markets provide insurance opportunities to merchants and processors against the risk of price fluctuation. In the case of a trader, an adverse price change brought by either supply or demand change affects the total value of his commitments; and the larger the value of his inventory, the larger the risk to which he is exposed. The futures

market provides a mechanism for the trader to lower the per unit inventory risk on his commitments in the cash market (where actual physical delivery of the commodity must eventually be made) through what is known as hedging. A trader is termed a hedger if his commitments in the cash market are offset by opposite commitments in the futures market. An example would be that of a grain elevator operator who buys wheat in the country and at the same time sells a futures contract for the same quantity of wheat. When his wheat is delivered later to the terminal market or to the processor in a normal market, he buys back his futures contract. Any change of price that occurred during the interval should have been cancelled out by mutually compensatory movements in his cash and futures holdings. The hedger thus hopes to protect himself against loss resulting from price changes by transferring the risk to a speculator who relies upon his skill in forecasting price movements.

For a better understanding of the process involved, the distinctive features of the cash market and the futures market should be made clear. The cash market may be either a spot market concerned with immediate physical delivery of the specified commodity or a forward market, where the delivery of the specified commodity is made at some later date. Futures markets, on the other hand, generally permit trading in a number of grades of the commodity to protect hedger sellers from being "cornered" by speculator buyers who might otherwise insist on delivery of a particular grade whose stocks are small. Since a number of alternative grades can be tendered, the futures market is not suitable for the acquisition of the physical commodity. For this reason, physical delivery of the commodities in fulfillment of the futures contract generally does not take place, and the contract is usually settled between buyers and sellers by paying the difference between the buying and selling price. Several futures contracts in a commodity are traded during a year. Thus, five wheat contracts, July, September, December, March, and May, and six soybean contracts, September, November, January, March, May and July are traded on the Board of Trade of the City of Chicago. The length of these contracts is for a period of about 10 months, and a contract for "September wheat" or "September soybean" indicates the month the contract matures.

Hedging as insurance

Though hedging is a form of insurance, it seldom provides perfect protection. The insurance is based on the fact that the cash and futures prices move together and are well correlated. The price spread between the cash and futures, however, is not invariant. The hedgers, therefore, run the risk that the price spread, known as the "basis," could move against them. The possibility of such an unfavourable movement in the basis is known as basis risk. Thus hedgers, through their commitment in the futures market, substitute basis risk for the price risk they would have taken in carrying unhedged stocks. It must be emphasized, however, that risk reduction is not the final objective with merchants and processors; what they seek to do is to maximize profits.

The availability of capital for financing the holding of inventories depends on whether they are hedged or not. The bankers' willingness to finance them increases with the proportion of the inventory that is hedged. For example, the banks may advance loans to the extent of only 50 percent of the value of unhedged inventories and 90 percent if they are all hedged, a difference explained by the fact that hedging reduces the risk on which the amount of the loan and the interest rate depend. Merchants and processors can therefore derive a twofold advantage from futures trading; they can insure against price decline and they can secure larger and cheaper loans from the banks.

The theory and practice of hedging. There are two rival hypotheses concerning the motives for and costs of hedging. The first of these, advanced by John Maynard Keynes and J.R. Hicks, suggests that risk reduction is the prime motive for hedging and that hedgers pay a risk premium to speculators for assuming risk. The Keynes-Hicks hypothesis states that under normal conditions in commodity markets, when demand, supply, and spot prices are expected to remain unchanged for some months to come and there is uncertainty in traders' minds regarding these expectations, the futures price, say, for one month's delivery is bound to be below the spot price that traders expect to prevail one month later. This condition exists because inventory holders would be ready to hedge themselves from the risk of price fluctuations by selling futures to speculators below the expected spot price. By selling futures below the expected spot price, according to the theory, inventory holders who hedge pay a risk premium to speculators.

The rival hypothesis of Holbrook Working maintains that hedging is done with the expectation of a profit from a favourable change in the spot-futures price relation, to simplify business decisions, and to cut costs, and not for the sake of reducing risk alone. Hedgers, according to Working, are arbitrageurs; *i.e.*, they take advantage of a temporary price difference between two markets to buy in one and sell in the other. They thus speculate on the basis and assume risk.

A compromise between these rival theories and a more balanced view regarding the need for hedging and the scope of hedging activities is that hedging is motivated by the desire to reduce risks, as suggested by the Keynes-Hicks theory, but that the levels of inventory held by merchants and processors are determined by expected hedging profits, as Working has emphasized.

The long and short hedger

There are two categories of hedgers in the futures market: they are called short and long hedgers. Short hedgers are merchants and processors who acquire inventories of the commodity in the spot market and who simultaneously sell an equivalent amount or less in the futures market. The hedgers in this case are said to be long on their spot transaction and short in the futures transaction. Wheat merchants or wheat flour mills who either have 100,000 bushels of wheat as inventory or have bought it for later delivery are said to short hedge if they sell 100,000 bushels of wheat in futures contracts. By holding inventories, both merchants and processors can make their purchases when it is most opportune and lower their transaction costs through fewer transactions. Another advantage to the processing firm in holding inventory is that it makes it possible to avoid interruption in production. It must be borne in mind that short hedgers do not normally deliver the physical commodity in fulfillment of the futures contract. They "lift the hedge" by repurchasing the futures contract at the prevailing futures price when they sell the raw material or the processed good in the spot market.

The merchants and processors do not generally hedge all their inventories for the sake of reduced risk. The decision on what part of inventories to hedge is based on their expectations relating to return from holding hedged and unhedged inventories in storage, given the cost incurred in both forms of inventory holding. The return per unit inventory to merchants and processors on their hedged inventories, when liquidated, is the change in the spot price less the change in the futures price and the storage costs. Their return on per unit unhedged inventory is the change in spot price less storage costs.

Long hedgers, in contrast, are merchants and processors who have made formal commitments to deliver a specified quantity of raw material or processed goods at a later date at a price currently agreed upon and who do not now have the stocks of the raw material necessary to fulfill their forward commitment. The parties who have made the commitment generally seek to hedge against the risk of price rise in the raw material between the time of making the forward contract and the time of acquiring the raw material stocks for fulfilling the contract. The hedging is done by buying futures contracts of the raw material equal in quantity to what is needed to fulfill the forward commitment.

The question arises under what circumstances the long hedger might prefer the purchase of futures to the alternative of immediately buying the raw material through spot or forward purchase to meet the obligations of his forward sale. He may prefer buying futures to buying in the cash market (spot or forward) if current cash prices are high because of scarcity. Generally there is an increase in the amount of long hedging when, as the season advances,

spot prices rise, inventory holdings fall, and the new crop is not yet available. Long hedging is not as risk-reducing as it may appear at first sight. The long hedger processor, for example, who buys raw material futures to satisfy his forward commitment of the processed good may find that the raw material delivered to him in futures is not of suitable grade and quality to meet the obligations of the forward sale. Quite often, therefore, he may sell his futures contract and purchase raw material of the grade needed. If the spot price of the raw material moves unfavourably relative to the price of the processed good sold forward by him, the long hedger actually increases the risk by buying futures instead of buying the raw material in the cash market. Long hedging, unlike short hedging, may serve to increase risk, and the total risk on long hedging increases with the size of the commitment.

The volume of short hedging tends to be large when stocks in commercial hands are large and when the cash price is below the futures price; a reversal in this situation brings a decline. Conversely, the volume of long hedging is large when stocks are small and the cash price is above the futures price. Short hedging has a marked seasonal pattern, reaching a peak when commercial stocks are largest and the basis is favourable and then declining as the season advances. The seasonal pattern is less marked in long hedging. Generally there is an excess of short over long hedging during the bulk of the crop year.

The speculator's role

Apart from hedgers, the futures market includes speculators, and these can also be classified in two categories, namely, long and short speculators. The long speculators are those who expect the price to rise above the current level and assume risks by purchasing futures contracts. Short speculators are those who expect the price to fall. They sell futures contracts. In a futures market the total short selling position, made up of short hedgers and short speculators, and the total long buying position, made up of long hedgers and long speculators, must always be equal. Any excess of short over long hedging must be balanced by an equal excess of long over short speculation. Since short hedging exceeds long hedging for most of the crop year, hedgers are generally short and speculators, therefore, are generally long.

Futures markets have flourished and become important in commodities where sizeable inventories have to be stored and carried forward for meeting the consumption needs of the entire season. Successful futures trading requires a large volume with low transaction costs and that spot and futures prices be well correlated in order to make hedging effective.

Chicago Board of Trade

Important futures markets. Based on the number and volume of commodities in which active futures trading exists, the United States occupies first place. The Chicago Board of Trade, the largest of the world's futures markets in terms of volume and value of business, is the centre for trading in wheat, corn, oats, rye, soybeans, soybean oil, and soybean meal. About 30 commodities in all are traded on organized exchanges in the United States. The wheat market in Minneapolis, the cotton and wool markets in New York City, and the markets in frozen pork bellies and live hogs in the midwestern United States are among them. The number of commodities in which futures trading takes place are far fewer outside the United States.

There are futures markets for wool in London, Paris, and Sydney; for cotton in Liverpool and Bombay; for sugar in London and Paris; for jute goods in Calcutta; for black pepper in Cochin, India; and for turmeric in Sāngli, India. As a result of government controls on futures markets and also of international commodity agreements, the volume of futures trading in several countries has been adversely affected. The commodity markets in Europe, with few exceptions, have been dormant since the end of World War II. Many of the Indian commodity markets, such as those in gur, jute, and oilseeds, which were once active, have met the same fate. The recurrent arguments in the United States, India, and elsewhere against the futures markets are that they encourage speculation and that the participation of speculators causes price instability. These arguments have led to the demand that markets be controlled or prohibited from functioning. To refute such allegations requires a comparison between price variations in the presence and absence of speculation, which is impossible for commodities that have futures markets, since it is not meaningful to say for these markets what the price would have been in the absence of speculation. (L.S.V.)

Markets for manufactures

The market for manufactured goods is what economists call "imperfect," because each company has its own style, its own reputation, and its own locations; and all of the arts of advertisement and salesmanship are devoted to making it even more imperfect by attracting buyers to particular brand names. Even small businesses that depend upon outside channels of retail distribution may have the final say in what prices they will charge, and great corporations can differentiate their goods in order to create demand for them.

In this type of market, supply normally is very elastic—that is, responsive to demand—in the short run. Stocks or inventories are held at some point in the chain of distribution; while stocks are running down or building up, there is time to change the level of production, and once a price has been set, it is rarely altered in response to moderate changes in demand. Even in a deep slump, defensive rings may often be formed to prevent price cutting.

In the long run, as well as in the short, supply is responsive to demand in the market for manufactures. It is easier to change the composition of a firm's output than it is to change the production of a mine or a plantation. And when changes in demand are not too rapid, gross profits from one plant can be siphoned off and invested in something quite different. When business is good, moreover, there is continual new investment so that productive capacity is adapted to meeting changing requirements. Workers themselves may not even be aware of changes in the final commodities to which their work contributes, and the level of wages for any grade of factory labour is very little affected by the fortunes of a particular market.

Financial markets

Along with a growth of trade in goods, there has been a proliferation of financial markets. A stock exchange is an organized market for dealing in the securities of businesses and governments. Currently, dealings in securities that came into being in the past predominate over dealings in new issues, and the greater part of industrial investment is financed by retention of profits. Instead of serving mainly as a channel for lending to industry, the chief functions of a stock exchange are to provide a convenient way for owners of property, inherited or newly saved, to place their wealth in income-yielding form, and to provide liquidity and security for them by making a market in which financial assets can readily be realized or redeployed. Dealings in a commodity market, as noted earlier, necessarily contain a speculative element; but in the market for securities, speculation overshadows all else. The art of speculation, as Keynes said, is "to anticipate what average opinion expects average opinion to be." The notorious instability of stock exchanges, with their disturbing effects upon the availability of finance for business and upon the nominal wealth of shareholders, may have repercussions in the market for real goods and services.

Stock markets and money markets

Another kind of financial market is the so-called money market. The money market is not an organized exchange; nor is it confined to money in the ordinary sense. The phrase refers to what might be called wholesale transactions in money and short-term credit carried on mainly by large commercial banks. Through the banking system, government authorities (say, the Bank of England or the United States Federal Reserve Board) have some power to control the market for money. But the more the authorities attempt to exercise their powers, the faster the money market develops new organs for bringing lenders and borrowers together and new types of transferrable obligations that are "almost money," in order to escape from control. (An example of this is the huge Eurocurrency and Eurobond markets in which money and financial instruments

are bought and sold independently of national monetary authorities.) (J.Ro.)

SECURITIES TRADING

Securities are written evidences of ownership giving their holders the right to demand and receive property not in their possession. The most common types of securities are stocks and bonds, of which there are many particular kinds designed to meet specialized needs. This article deals mainly with the buying and selling of securities issued by private corporations. (The securities issued by governments are discussed in the article GOVERNMENT FINANCE.)

Types of corporate securities. Corporations create two kinds of securities: bonds, representing debt, and stocks, representing ownership or equity interest in their operations. (In Great Britain, the term stock ordinarily refers to a loan, whereas the equity segment is called a share.)

Bonds. The bond, as a debt instrument, represents the promise of a corporation to pay a fixed sum at a specified maturity date, and interest at regular intervals until then. Bonds may be registered in the names of designated parties, as payees, though more often, in order to facilitate handling, they are made payable to the "bearer." The bondholder usually receives his interest by redeeming attached coupons.

Since it could be difficult for a corporation to pay all of its bonds at one time, it is common practice to pay them gradually through serial maturity dates or through a sinking fund, under which arrangement a specified portion of earnings is regularly set aside and applied to the retirement of the bonds. In addition, bonds frequently

Calling bonds

may be "called" at the option of the company, so that the corporation can take advantage of declining interest rates by selling new bonds at more favourable terms and using these funds to eliminate older outstanding issues. In order to guarantee the earnings of investors, however, bonds may be noncallable for a specified period, perhaps for five or 10 years, and their redemption price may be made equal to the face amount plus a "premium" amount that declines as the bond approaches its maturity date.

The principal type of bond is a mortgage bond, which represents a claim on specified real property. This protection ordinarily results in the holders' receiving priority treatment in the event that financial difficulties lead to a reorganization. Another type is a collateral trust bond, in which the security consists of intangible property, usually stocks and bonds owned by the corporation. Railroads and other transportation companies sometimes finance the purchase of rolling stock with equipment obligations, in which the security is the rolling stock itself.

Although in the United States the term debentures ordinarily refers to relatively long-term unsecured obligations, in other countries it is used to describe any type of corporate obligation, and "bond" more often refers to loans issued by public authorities.

Corporations have developed hybrid obligations to meet varying circumstances. One of the most important of these is the convertible bond, which can be exchanged for common shares at specified prices that may gradually rise over time. Such a bond may be used as a financing device to obtain funds at a low interest rate during the initial stages of a project, when income is likely to be low, and encourage conversion of the debt to stock as earnings rise. A convertible bond may also prove appealing during periods of market uncertainty, when investors obtain the price protection afforded by the bond segment without materially sacrificing possible gains provided by the stock feature; if the price of such a bond momentarily falls below its common-stock equivalent, persons who seek to profit by differentials in equivalent securities will buy the undervalued bond and sell the overvalued stock, effecting delivery on the stock by borrowing the required number of shares (selling short) and eventually converting the bonds in order to obtain the shares to return to the lender.

Income bonds

Another of the hybrid types is the income bond, which has a fixed maturity but on which interest is paid only if it is earned. These bonds developed in the United States out of railroad reorganizations, when investors holding defaulted bonds were willing to accept an income obligation in exchange for their own securities because of its bond form; the issuer for his part was less vulnerable to the danger of another bankruptcy because interest on the new income bonds was contingent on earnings.

Still another hybrid form is the linked bond, in which the value of the principal, and sometimes the amount of interest as well, is linked to some standard of value such as commodity prices, a cost of living index, a foreign currency, or a combination of these. Although the principle of linkage is old, bonds of this sort received their major impetus during the inflationary periods after World Wars I and II. In recent years they have had the most use in countries in which the pressures of inflation have been sufficiently strong to deter investors from buying fixed-income obligations.

Stock. Those who provide the risk capital for a corporate venture are given stock, representing their ownership interest in the enterprise. The holder of stock has certain rights that are defined by the charter and bylaws of the corporation as well as by the laws of the country or state in which it is chartered. Typically these include the right to share in dividends and other distributions, to vote for directors and fundamental corporate changes, and to inspect the books of the corporation, and, less frequently, the "pre-emptive right" to subscribe to any new issue of stock. The stockholder's interest is divided into units of participation, called shares.

A stock certificate ordinarily is given as documentary evidence of share ownership. Originally this was its primary function; but as interest in securities grew and the capital market evolved, the role of the certificate gradually changed until it became, as it is now, an important instrument for the transfer of title. In some European countries the stock certificate is commonly held in bearer form and is negotiable without endorsement. To avoid loss, the certificates are likely to be entrusted to commercial banks or a clearing agency that is able to handle much of the transfer function through offsetting transactions and bookkeeping entries. In the United States, certificates usually are registered in the name of the owner or in a "street name"—the name of the owner's broker or bank; the bank may for legal reasons use the name of another person, known as a "nominee." When a certificate is held in the name of a broker or bank nominee, the institution is able to make delivery more readily and the transfer process is facilitated. Investors, for legal or personal reasons, may prefer to keep the certificates in their own names.

A corporation may endow different kinds or classes of stock with different rights. Preferred stock has priority with respect to dividends and, if the corporation is dissolved, to the division of assets. Dividends on preferred stock usually are paid at a fixed rate and are often cumulated in the event the corporation finds it necessary to omit a distribution. In the latter circumstance the full deficiency must be cleared before payments may be made on the common shares. Participating preferred stock, in addition to stipulated dividends, receives a share of whatever earnings are paid to the common stock. Participation is usually resorted to as an inducement to investors when the corporation is financially weak. Although a preferred issue has no maturity date, it may be given redemption terms much like those of a bond, including a conversion privilege and a sinking fund. Preferred stockholders may or may not be allowed to vote equally with common stockholders on some or all propositions or more characteristically may vote only upon the occurrence of some prescribed condition, such as the default of a specified number of dividend payments.

Common stock, in some countries called ordinary shares, represents a residual interest in the earnings and assets of a corporation. Whereas distributions to bonds or preferred stock are ordinarily fixed, dividends paid on common stock are set at the time of payment by the directors and tend to vary with earnings. The market price of common stock is likely to move in a relatively wide range, depending on investors' expectations of earnings in the future.

Options. An option contract is an agreement enabling the holder to buy a security at a fixed price for a limited period of time. One form of option contract is the stock

Warrants

purchase warrant, which entitles the owner to buy shares of common stock at designated prices and according to a prescribed ratio. Warrants are often used to enhance the salability of a senior security, and sometimes as part of the compensation paid to bankers who market new issues.

Another use of the option contract is the employee stock option. This is used to compensate key executives and other employees; it is normally subject to a variety of restrictions and is generally nontransferrable. Stock rights, like warrants, are transferrable privileges permitting stockholders to buy another security or a portion thereof at a specified price for an indicated period of time. The stock right allows stockholders to subscribe to additional shares of stock in proportion to their present holdings. Stock rights usually have a shorter life-span than warrants, and their subscription price is below, rather than above, the market price of the common stock.

The marketing of new issues. The marketing of securities is an essential link in the mechanism that transfers capital funds from savers to users. The transfer may involve intermediaries such as savings banks, insurance companies, or investment trusts. The ultimate user of the funds may be a corporation or any of the various levels of government from municipalities to national states.

The growth of public debt throughout the world has made governments increasingly important participants in the markets for new securities. They have had to develop financing techniques with careful attention to their influence on the markets for nongovernmental securities. The treasuries must carefully study interest rates, yield patterns, terms of financing, and the distribution of holdings among investors.

Local governments are usually subject to various statutory restrictions that must be carefully observed when offering a new issue for sale. Local government bonds are distributed through investment bankers who buy them and reoffer them to the public at higher prices and correspondingly lower yields. Sometimes the terms of the offer are negotiated. In the United States, however, a more prevalent means of selling state and local bonds is through competitive bidding, in which the issuer announces a contemplated offering of bonds for a designated amount, with specified maturity dates, and for certain purposes. Syndicates of investment bankers are formed to bid on the issue, and the award is made to the group providing the most favourable terms. The winning syndicate then reoffers the bonds to the public at prices carefully tailored to be competitive with comparable obligations already on the market and to provide a suitable profit margin.

Marketing corporation securities

The financial manager of a company requiring additional funds has a number of alternative courses of action open to him. He may do all of his financing through commercial banks by means of loans and revolving credit arrangements that, in essence, are formalized lines of credit. Or, he may prefer to raise capital through the sale of securities. If he chooses to do the latter, he may undertake a private sale with an institutional investor such as an insurance company, permitting him to avoid both the complicated procedures of a public distribution and the risks of unsettled market conditions. On the other hand, a private placement of this sort deprives the issuer of the favourable publicity flowing from a successful public offering; it may not afford sufficient resources for very large firms with continuing demands for capital; and it involves rather restrictive legal requirements.

A company that elects to float its securities publicly in the capital market will ordinarily utilize the services of an investment banker. The investment banker may buy the securities from the issuer and seek a profit by selling them at a higher price to the public, thereby assuming the market risks. If the issue is large, the originating investment banker may invite other houses to join with him in purchasing the issue from the company, while to facilitate disposal he may form a selling group to take over the issue from the buying firms for resale to the public. In lieu of buying the securities from the issuer, the investment banker may act as an agent and receive a commission on the amount sold. If the issuer negotiates the selection of an investment banker, the banker will serve as financial counsel and offer advice on the timing and terms of the new issue. If the selection is by competitive bidding, the relationship is likely to be more impersonal.

An accepted principle of modern finance is that investors are entitled to knowledge about the issuer in order to appraise the quality of the securities offered. A number of countries now require issuers to file registration statements and provide written prospectuses.

The security markets of Europe do not have the aggressive investment-banking machinery developed in the United States. European commercial banks, on the other hand, play a much more important role in financing the needs of industry than do commercial banks in the United States and Great Britain.

In the 1960s, a number of industrial nations faced increasing difficulties in meeting their financing needs through local capital markets. Several issuers began to float securities that were payable in any of 17 different European currencies. This marked what might be called the beginning of an "international securities" market. Efforts were also made to issue bonds on a parallel basis in different countries with each portion denominated in the currency of the country in which it was sold. For various legal and technical reasons, these methods did not attract a wide following.

Another factor that hastened the growth of a European securities market was the balance of payments problem confronting the United States in the 1960s. Certain legislative enactments substantially shut the capital market of the U.S. to foreign issuers; and other restraints were imposed on foreign lending by United States financial institutions and on direct foreign investment by United States corporations. As a result, a number of multinational corporations headquartered in the United States were forced to seek financing in overseas securities markets for the expanding business of their foreign subsidiaries. United States and foreign investment bankers joined in syndicates to float these securities. The process was facilitated by the growth of an international market in Eurodollars, representing claims on dollars deposited in European banks. The bulk of the new bonds offered abroad were denominated in Eurodollars.

Eurodollars market

During the period 1957–65, when this new European market came into being, the volume of foreign bonds issued publicly rose from $492,600,000 to $1,489,500,000. The principal and most consistent borrowers were in Canada, Australia, Japan, Norway, Israel, Denmark, and New Zealand. In all of these countries, the major borrower was the national government, except in Canada, where the political subdivisions were the major borrowers. In West Germany, Great Britain, and the United States, the only borrowers in international markets were private units.

The machinery of securities trading. Organized securities markets and stock exchanges are a product of economic development. In the early years of economic growth, most of a country's industrial units are small and their capital requirements relatively modest. The rate of saving is low, and institutions for channelling private savings into investment are generally lacking. As the economy progresses and national income grows, new institutions enter the financial picture to direct the mounting volume of savings into productive outlets. The appearance of growing numbers of individual and institutional investors creates a need for trading markets to speed up transactions and enable stockholders swiftly and easily to convert their holdings to cash.

At this stage of development, corporations usually meet less of their financing needs through direct sales of securities in the new issue market and obtain a larger percentage through reinvesting their own earnings. This plowing back of earnings is not insensitive to the judgment of investors: if the prospects of a company are good, investors bid up the price of its shares in the trading market and show a willingness to forego dividends for the possibility of long-term capital gains achieved through internal growth. Thus, when a company is able to finance its expansion by means of reinvested earnings rather than by new stock issues, the trading segment becomes the more important aspect of the capital market.

The development of stock exchanges

History. Stock exchanges grew out of early trading activities in agricultural and other commodities. Traders in European fairs in the Middle Ages found it convenient to use credit, which required the supporting documents of drafts, notes, and bills of exchange. The French stock exchange may be traced as far back as the 12th century, when trading occurred in commercial bills of exchange. To regulate these incipient markets, Philip the Fair (1268–1314) created the profession of *courratier de change,* the forerunner of the modern French stockbroker, or *agent de change.* At about the same period in Bruges, then a prosperous centre of the Low Countries, merchants took to gathering in front of the house of the Van der Buerse family to engage in trading. From this custom, the name of the family became identified with trading, and eventually "bourse" came to signify a stock exchange. From similar roots in trade and commerce, the institutional beginnings of stock exchanges appeared during the 16th and 17th centuries in other great trading centres throughout the world—Amsterdam, Great Britain, Denmark, Germany.

The growth of trade created a need for banks and insurance companies. Political developments caused governments to seek new sources of funds. This combination of expanding activity and intermittent capital shortages stimulated the early issuers of securities—governments, banks, insurance companies, and some joint-stock enterprises, particularly the great trading companies. From the existing exchanges for commercial bills and notes, it was an easy and logical transition to the establishment of stock exchanges for securities. By the early 1600s, shares of the Dutch East India Company were being traded in Amsterdam; in 1773, London stock dealers who had previously been meeting in coffeehouses moved into their own building; and by the 19th century, trading in securities on a formal basis was common in the industrialized nations.

The evolution of stock exchanges continued. In Great Britain, progress has for the most part been internal and voluntary; the London Stock Exchange has regulated its own activities. The French stock exchanges, in contrast, are directly subject to law, and the operations of the *agents de change* have been affected by national decrees. At one time, there were three markets for securities in Paris: an official market called the Parquet (the "floor"); a semiofficial market, the Coulisse (the "wing"); and the Hors Côté (the "outside"), an unregulated market in unlisted securities. In 1929, the Hors Côté was subjected to official regulation and in the following decade its activities were absorbed into the Coulisse, which in turn was combined with the Parquet in a reorganization in 1961. In Belgium the exchanges have had a mixed history. Strict governmental controls were imposed in 1801 and not removed until 1867. Following the economic crisis of 1929–34, the pendulum swung the other way, and the exchanges were once more placed under the control of central authority. In Switzerland, the exchanges have been governed by cantonal (state) law.

Historical events have left their mark upon the development of stock exchanges in some countries. Mining, rather than trade and commerce, was the impelling influence in the establishment of stock exchanges in South Africa and Canada. In Germany, the Berlin Stock Exchange lost its dominant role after World War II, and its position was assumed by exchanges in Frankfurt and Düsseldorf. The Japanese securities markets were revolutionized following World War II, when a new securities law was enacted patterned after the U.S. model. A campaign to distribute stock formerly held by the large *zaibatsu* (family-owned combines) and semigovernment corporations greatly increased public stock ownership, which in turn contributed to the considerable growth of trading on the nine Japanese exchanges. Another post-World War II development was the interest of the governments of developing countries in the use of stock exchanges to facilitate external financing.

Securities markets in the United States began with speculative trading in issues of the new government. In 1791, the country's first stock exchange was established in Philadelphia, then the leading city in domestic and foreign trade. An exchange in New York was set up in 1792, when 24 merchants and brokers decided to charge commissions while acting as agents for other persons and to give preference to each other in their negotiations. They did much of their trading under a tree at 68 Wall Street. Government securities formed the basis of the early trading. Stocks of banks and insurance companies added to the volume of transactions. The building of roads and canals brought more securities to the market. In 1817 the New York brokers decided to organize formally as the New York Stock and Exchange Board. Thereafter, the stock market grew with the industrialization of the country. In 1863, the New York Stock Exchange adopted its present name. During the Civil War additional exchanges were organized, one of them the forerunner of the present American Stock Exchange, the second largest stock market in the country.

New York Stock Exchange

Organization. All stock exchanges perform similar functions with respect to the listing, trading, and clearing of securities. They differ in their administrative machinery for handling these functions.

The London Stock Exchange, the largest in the world in terms of the number and variety of domestic and international securities traded, is an independent institution not subject to governmental regulation. It resembles a private club with its own constitution and operating rules, administered by a council that, except for the government broker who is an ex officio nonvoting member, is elected by the membership. Operating responsibility is vested in the secretary and his staff.

In the United States, as in Great Britain, the government does not participate directly in the operations of the exchanges. Since 1933, however, Congress has enacted half a dozen measures that in one way or another affect the securities market. The most important are the Securities Act of 1933, which is primarily concerned with the new-issue market, and the Securities Exchange Act of 1934, which is directed toward the trading market. The latter requires that every stock exchange register with the Securities and Exchange Commission (SEC) as a national securities exchange, unless it is exempted because of the limited volume of its transactions, and that it conform to certain rules in its trading practices. This relationship between the stock exchanges and the SEC is peculiar to the United States; it involves a sort of administrative partnership between the exchanges as private associations—but functioning as quasi-public institutions—and the government. The exchanges generally may adopt policies and issue regulations governing their own operations but are subject to SEC intercession in the event that the Commission believes modifications are required in the public interest.

Most European exchanges are also subject to some form of governmental regulation. The Amsterdam Stock Exchange is a private organization, relatively free to regulate the activities of the market, but the Minister of Finance exercises some supervision under existing legislation. The Zürich exchange is governed by a board of elected members that determines general policy and coordinates the work of the exchange's committees. Of these, the Zürich Cantonal Committee, which directs dealings on the floor of the exchange, is chaired by the head of the Finance Department of the State of Zürich. Although the Frankfurt Stock Exchange is under the direct administration of a Board of Governors elected by its own members, the rules of the exchange must be approved by the authorities of the state of Hesse; and the official specialists, each responsible for the trading in certain securities, are appointed by the Minister of Finance in the state of Hesse. In Brussels the Ministry of Finance is involved in the appointment of members to major committees, while a governmental representative is attached to each exchange to supervise the observance of all rules and laws; in addition, the Banking Commission that is nominated by the government has substantial powers over the admission of securities to public trading. The policy-making Exchange Commission of the Paris bourse is headed by the Governor of the Banque de France, while the regular members are chosen by the Ministry of Finance; the *agents de change* who supervise the trading process are semigovernmental officials. New members of the Italian stock exchanges are appointed by the government from a list of candidates as a result of competitive examinations and therefore have some public status.

Membership requirements of stock exchanges

Since 1953, membership in the New York Stock Exchange has been limited to 1,366. Only individuals may be members, but they may be partners or stockholders of organizations that do business with the public. Their organizations in such cases are known as member firms. The exchange supervises and regulates member firms in what it considers to be the public interest: a majority of the owners must be engaged primarily in the business of brokers or dealers in securities; exchange approval is required of any shareholder with a 5 percent interest in a member corporation; and all principal officers and directors who are active in the firm must be members or allied members of the exchange. An allied member is subject to the rules of the exchange but does not have the right to engage in transactions on the floor.

To become a member, an individual must acquire, with the approval of the board of governors, a "seat" from a present member or from the estate of a deceased one. Before granting approval, the exchange will investigate such matters as the applicant's past record and financial standing; he will also have to pass an examination demonstrating his knowledge of the securities field.

There are several kinds of brokers on the floor of the exchange. They include the commission broker who executes customer orders placed at or near the current market price; the specialist in one or more issues who, as a broker, executes limited orders for other members and, as a dealer, buys and sells securities for his own account; floor brokers, or "two-dollar" brokers, who execute orders for other brokers at a commission but have no contact with the public; brokers associated with odd-lot firms, who undertake to buy or sell in quantities other than the standard 100-share lot; and "registered traders" who buy and sell for their own account.

To become a member of the London Stock Exchange, an individual must acquire a "nomination" from a retiring member at a price that varies with demand and supply. Every applicant must be approved by at least three-quarters of the stock exchange council. A member may be a broker, dealing as an agent of the public, or a jobber, dealing for his own account with other brokers or jobbers.

Membership in the Paris stock exchange is limited to 85 *agents de change* who supervise activity while the actual work of trading and executing orders is done by their employees and those of the exchange. To become an *agent de change,* an applicant must meet prescribed standards of education and experience as well as pass a written examination. He must be nominated by a retiring member or the heirs of a deceased member and make a deposit guaranty. He is formally appointed by the Minister of Finance.

Other European exchanges set eligibility requirements of character, experience, and financial standing, and some have educational requirements as well. In Brussels, in addition to the completion of six consecutive years in a broker's office, a candidate must have a degree in commercial science or economics and pass a professional examination. In Germany, Switzerland, and Sweden, the brokerage business is dominated by banks.

Members of Japanese exchanges must be corporations doing a business in securities. There are two kinds of members: regular members, who buy and sell for customers or for their own accounts, and *saitori,* who act principally as intermediaries for regular members.

Trading procedures. Most stock exchanges are auction markets, in which prices are determined by competitive bidding. In very large, active markets, the auction is continuous, occurring throughout the day's trading session and for any security in which there is buying and selling interest. In smaller markets the names of the listed stocks may be submitted in some form of rotation, with the auction occurring at that time; this process is described as a "call market."

Trading methods on all the exchanges in the United States are similar. In a typical transaction for a security listed on the New York Stock Exchange, a customer gives an order to an employee in a branch or correspondent office of a member firm, who transmits it either indirectly through the firm's New York office or, as is becoming increasingly common, directly to a receiving clerk on the floor of the exchange. The receiving clerk summons the firm's floor broker, who takes the order, goes to the post where the stock is traded, and participates in an auction procedure as either buyer or seller. If the order is not a market order calling for immediate action, the broker turns it over to an appropriate specialist who will execute it when an indicated price is reached.

Floor broker

As in any auction market, securities are sold to the broker bidding the highest price and bought from the broker offering the lowest price. Since the market is continuous, buyers and sellers are constantly competing with each other. In the New York Stock Exchange, the specialist plays an important role. As a principal, he has the responsibility of buying and selling for his own account, thereby providing a stabilizing influence; as an agent, he represents other brokers on both sides of the market when they have orders at prices that cannot be readily executed.

With the growing demand for stocks on the part of institutions such as insurance companies, mutual funds, pension funds, and so forth, the size of orders consummated on the New York Stock Exchange has grown. The common way of handling these big blocks on the floor of the exchange has been to break them into smaller orders executed over a period of time. Another method is to assemble matching orders in advance and then "cross" them, executing the purchase or sale at current prices in accordance with prescribed rules; since the broker initially may have obtained the matching orders off the floor, this procedure assumes some of the aspects of a negotiated rather than a pure auction transaction. It is only a step from this to so-called block positioning, in which the broker functions as a principal and actually buys the block from the seller and distributes the securities over a period of time on the floor of the exchange.

When none of these methods appears feasible, the exchange permits certain special procedures. A *secondary distribution* of stock resembles the underwriting of a new issue, the block being handled by a selling group or syndicate off the floor after trading hours, at a price regulated by the exchange. In an *exchange distribution* a member firm accumulates the necessary buy orders and then crosses them on the floor. This is distinguished from an ordinary "cross" because the selling broker may provide extra compensation to his own registered representatives and to other participating firms. A *special offering* is the offering of a block through the facilities of the exchange at a price not in excess of the last sale or the current offer, whichever is lower, but not below the current bid unless special permission is obtained. The terms of the offer are flashed on the tape. The offerer agrees to pay a special commission. A *specialist block purchase* permits the specialist to buy a block outside the regular market procedure, at a price that is somewhat below the current bid.

Brokers and jobbers

Trading on the London Stock Exchange is carried on through a unique system of brokers and jobbers. A broker acts as an agent for his customers; a jobber, or dealer, transacts business on the floor of the exchange but does not deal with the public. A customer gives an order to a brokerage house, which relays it to the floor for execution. The receiving broker goes to the area where the security is traded and seeks a jobber stationed in the vicinity who specializes in the particular issue. The jobber serves only in the capacity of a principal, buying and selling for his own account and dealing only with brokers or other jobbers. The broker asks the jobber's current prices without revealing whether he is interested in buying or selling. The broker may seek to narrow the spread between the bid and ask quotations or he may approach another jobber handling the same issue and undertake the same bargaining process. Eventually, when satisfied that he has obtained the best possible price for his client, the broker will complete the bargain.

A broker is compensated by the commission received from the customer. The jobber seeks to maximize his profitable business by adjusting his buying and selling prices. As the ultimate dealer in the London market, the jobber's activities provide a stabilizing factor, but unlike the specialist on the New York Stock Exchange, the jobber is under no obligation to help support prices. The grow-

ing importance of institutional customers has increased the size of transactions in the London market as it has in the U.S., and therefore the jobber has been compelled to risk larger sums. To offset this risk, arrangements for a particularly large order may be negotiated beforehand and the transaction put through the floor as a matter of procedure, with the jobber accepting a minimum "turn." Although the jobbing system provides a continuous market, it does not employ the auction bidding of the New York exchange.

The trading procedures of other major exchanges throughout the world employ the principles that have been described above, although they vary in their application of them. In the exchanges of Paris, Brussels, Copenhagen, Stockholm, and Zürich, some form of auction system is employed: prices are established through bids and offers made on specific securities at particular periods of time. In Tokyo, trading is continuous and orders are consummated through the *saitori* members, who keep order sheets on all transactions. Unlike the specialist on the New York exchange or the jobber in London, however, the *saitori* does not trade for his own account but serves only as an intermediary between regular members. In Amsterdam, trading in active securities is done directly between members during designated trading periods; specialists function as intermediaries between buyers and sellers.

Types of orders. The simplest method of buying stock is through the *market order.* This is an order to buy or sell a stated amount of a security at the most advantageous price obtainable after the order reaches the trading floor. A *limit* (or *limited*) *order* is an order to buy or sell a stated amount of a security when it reaches a specified price or a better one if it is obtainable after the order comes to the trading floor. In the Amsterdam market, the device of the "middle price" is used: an investor who gives a limit order before the opening will have it executed at the day's median level, or at a price that is better than the limit, whichever is found to be more advantageous to the client.

There are other more specialized types of orders. A *stop order* or *stop-loss order* is an order to purchase or sell a security after a designated price is reached or passed, when it then becomes a market order. It differs from the limit order in that it is designed to protect the customer from market reversals; the stop price is not necessarily the price at which the order will be executed, particularly if the market is changing rapidly. This type of order does not lend itself to the London jobbing system.

An important method of trading in stock is through the buying and selling of options. The most common option contracts are puts and calls. *A put* is a contract that permits the holder to deliver to the purchaser a specified number of shares of stock at a fixed price within a designated period of time, say six months; a *call* entitles him to buy shares from the seller within a given period. For example, a person who buys a stock hoping to sell it later at a higher price may also buy a put as a hedge against a fall in price. The put enables him to sell the stock at the price for which he bought it. If the stock rises he need not use the option and loses only the price of its purchase. Option trading is common in Brussels, Paris, London, and the United States.

Unorganized, or over-the-counter, markets

In the early days of securities trading, stocks and bonds were often bought at private banking houses in the same way that commodities might be purchased over the counter of a general store. This was the origin of the term "over-the-counter." It is used today to mean all securities transactions that are handled outside the exchanges. Increasingly, this market is being subjected to regulation. The extent and nature of the over-the-counter market varies throughout the world. In the United Kingdom, there is no over-the-counter market as such. In the Netherlands, transactions are illegal if they do not involve a member of the Amsterdam exchange or one of its provincial branches as an intermediary, except with the permission of the Ministry of Finance. On the Paris bourse, one post is provided for trading in unlisted issues. In Belgium, the stock exchange committee organizes, at least once a month, public sales of stocks that are not officially quoted. In Japan a second security section has been introduced into the major exchanges to provide more effective trading procedures for over-the-counter transactions.

In the United States, the over-the-counter market includes most federal, state, and municipal issues as well as a large variety of corporate stocks and bonds. The National Quotation Bureau, which compiles over-the-counter prices, has furnished quotations on approximately 26,000 over-the-counter stocks. In early 1971, a major development occurred with the introduction of current, computerized quotations on a number of active stocks.

Transactions in the over-the-counter market are executed through a large number of broker-dealers with a complex network of private wires and telephone lines. Their operations are subject to the rules of the National Association of Securities Dealers, Inc., a self-regulating body created in 1939. In 1964 the Congress extended to the larger over-the-counter companies the same requirements as to periodic reporting, proxy solicitation, and insider trading that are applied to dealers in listed stocks.

The over-the-counter market is a negotiated market, as distinguished from the auction markets for listed securities. An investor desiring to trade an over-the-counter security gives his order to a broker functioning as a retailer, who ordinarily shops among various firms to obtain the best possible price.

Because of the difficulty that institutions often experience in disposing of large blocks of listed securities on the exchanges, nonmember firms have set up over-the-counter markets in these issues—principally in those listed on the New York Stock Exchange. Although such transactions are conducted within the framework of the over-the-counter market, their prices are tied to those on the Exchange. Accordingly, this form of trading has been labelled the "third market." There is now also a "fourth market," consisting of direct transactions between investors without an intermediary. This market also had its origins in the need of the institutions to find ways of executing large transactions. Impetus to such direct dealings has been given by the development of computerized systems to bring together large traders.

The structure of demand for securities. Interest in the ownership of securities has increased greatly in recent decades. Inflationary tendencies have directed attention to stocks as a means of offsetting rising prices. Stock exchanges have cultivated investors through public relations programs. Government regulation has strengthened public confidence in stock trading procedures. Many governments have given support to the capital markets in order to facilitate business financing.

The distribution of stock ownership

In the United States, in addition to the millions of individuals who own shares of publicly held corporations, many others own shares indirectly through institutions that are large holders of stock, such as investment companies and pension funds. It is difficult to obtain figures for other countries. A major problem of developing countries has been the absence of investors able and willing to buy shares. Many investors in these countries have preferred to place their funds in tangible assets such as land.

Institutions such as insurance companies, mutual funds, pension funds, foundations, and universities have grown very important in the security markets of the United States. Because of their financial responsibilities to others, these institutions have characteristically followed conservative investment policies stressing the purchase of fixed-income securities. The long-term trend toward inflation, along with mounting stock prices, has led the institutions to look more favourably upon common stocks.

Among the most rapidly growing institutions are the mutual funds. Technically, these are known as open-end investment companies because the number of their shares outstanding constantly changes as new shares are sold to investors and old ones redeemed.

Dynamics of the securities markets. Over a long-term period, the movements of stock prices and of general business indicators tend to parallel each other. In studies of business cycles, it has been found that stock prices tend to reach their cyclical peaks and troughs somewhat ahead of general business indicators, and these are therefore generally classified as "leading indicators."

Long-term and short-term movements of stock prices

The price of a stock reflects the present value of expected future earnings, and the profits of a firm are strongly influenced by the general level of economic activity. The tendency of stocks to lead business may be attributable to investors' preoccupation with the future. Over the years, the trend of stock prices has been upward; since World War II the upward cycles has tended to be of longer duration, while declines have been relatively shorter. Within the generally expansionary movement, changes in share values of specific companies have been mixed, some showing striking long-term gains while others have suffered losses.

Dramatic events sometimes have a special influence on the psychology of investors, driving stock prices down despite improving business conditions. For example, between the fall of 1940 and the spring of 1942, the period immediately prior to and after the entry of the United States into World War II, U.S. stock prices dropped swiftly despite a continued revival of economic activity. In other cases the reasons for a fall in stock prices are not easy to discover.

Stock prices also experience daily changes of substantial size. Technical market analysts attempt to predict these changes by studying patterns in stock prices. Many theorists, however, claim that in a highly competitive market, prices fluctuate primarily as a result of new information that is not likely to appear in any organized fashion; they maintain that successive price movements are independent of each other and take place in a random fashion.

As investors' expectations change over time, their attitudes toward different types of stock change. Buoyant investors lean toward growth stocks, the value of which is expected to increase rapidly; when uncertainty prevails, the preference is for more conservative issues with stable records of earnings. Within any given period, investors' choices of particular stocks vary with their judgments of the related companies.

MONEY MARKET

The functions of a money market

Every country with a monetary system of its own has to have some kind of market in which dealers in bills, notes, and other forms of short-term credit can buy and sell. The "money market" is a set of institutions or arrangements for handling what might be called wholesale transactions in money and short-term credit. The need for such facilities arises in much the same way that a similar need does in connection with the distribution of any of the products of a diversified economy to their final users at the retail level. If the retailer is to provide reasonably adequate service to his customers, he must have active contacts with others who specialize in making or handling bulk quantities of whatever is his stock-in-trade. The money market is made up of specialized facilities of exactly this kind. It exists for the purpose of improving the ability of the retailers of financial services—commercial banks, savings institutions, investment houses, lending agencies, and even governments—to do their job. It has little if any contact with the individuals or firms who maintain accounts with these various retailers or purchase their securities or borrow from them.

The elemental functions of a money market must be performed in any kind of modern economy, even one that is largely planned or socialist, but the arrangements in socialist countries do not ordinarily take the form of a market. Money markets exist in countries that use market processes rather than planned allocations to distribute most of their primary resources among alternative uses. The general distinguishing feature of a money market is that it relies upon open competition among those who are bulk suppliers of funds at any particular time and among those seeking bulk funds, to work out the best practicable distribution of the existing total volume of such funds.

In their market transactions, those with bulk supplies of funds or demands for them, rely on groups of intermediaries who act as brokers or dealers. The characteristics of these middlemen, the services they perform, and their relationship to other parts of the financial mechanism vary widely from country to country. In many countries there is no single meeting place where the middlemen get together, yet in most countries the contacts among all participants are sufficiently open and free to assure each supplier or user of funds that he will get or pay a price that fairly reflects all of the influences (including his own) that are currently affecting the whole supply and the whole demand. In nearly all cases, moreover, the unifying force of competition is reflected at any given moment in a common price (that is, rate of interest) for similar transactions. Continuous fluctuations in the money market rates of interest result from changes in the pressure of available supplies of funds upon the market and in the pull of current demands upon the market.

Banks and the money market. *Commercial banks.* Commercial banks are at the centre of most money markets, as both suppliers and users of funds, and in many markets a few large commercial banks serve also as middlemen. These banks have a unique place because it is their role to furnish an important part of the money supply. In some countries they do this by issuing their own notes, which circulate as part of the hand-to-hand currency. More often, however, it is checking accounts at commercial banks that constitute the major part of the country's money supply. In either case, the outstanding supply of bank money is in continual circulation, and any given bank may at any time have more funds coming in than going out, while at another time the outflow may be the larger. It is through the facilities of the money market that these net excesses and shortages are redistributed, so that the banking system as a whole can at all times provide the means of payment required for carrying on each country's business.

In the course of issuing money the commercial banks also actually create it by expanding their deposits, but they are not at liberty to create all that they may wish whenever they wish, for the total is limited by the volume of bank reserves and by the prevailing ratio between these reserves and bank deposits—a ratio that is set by law, regulation, or custom. The volume of reserves is controlled and varied by the central bank (such as the Bank of England, the Bank of France, or the Federal Reserve System in the U.S.), which is usually a governmental institution, is always charged with governmental duties, and almost invariably carries out a major part of its operations in the money market.

Volume of reserves

Central banks. The reserves of the commercial banks, which are continually being redistributed through the facilities of the money market, are in fact mainly deposit balances that these commercial banks have on the books of the central bank or notes issued by the central bank, which the commercial banks keep in their own vaults. As the central bank acquires additional assets, it pays for them by crediting depositors' accounts or by issuing its own notes; thus the potential volume of commercial bank reserves is enlarged. With more reserves, the commercial banks can make additional loans or investments, paying for them by entering credits to depositors' accounts on their books. And in that way the money supply is increased. It may be reduced by reversing the sequence. The central bank can sell some of its marketable assets in the money market or in markets closely interrelated with the money market; payment will be made by drawing down some of the commercial bank reserve balances on its books; and with smaller reserves remaining, the commercial banks will have to sell or reduce some of their investments or their loans. That, in turn, results in a shrinkage of the outstanding money supply. Central bank operations of this kind are called open-market operations.

The central bank may also increase bank reserves by making loans to the banks or to such intermediaries as bill dealers or dealers in government securities. Reduction of these loans correspondingly reduces bank reserves. Although the mechanics of these lending procedures vary widely among countries, all have one feature in common: the central bank establishes an interest rate for such borrowing—the bank rate or discount rate—pivotally significant in the structure of money market rates.

Money market assets may range from those with the highest form of liquidity—deposits at the central bank—through bank deposits to various forms of short-term paper such as treasury bills, dealers' loans, bankers' accep-

tances, and commercial paper, and including government securities of longer maturity and other kinds of credit instruments eligible for advances or rediscount at the central bank. Although details vary among countries, the touchstone of any money market asset other than money itself is its closeness—*i.e.*, the degree of its substitutability for money. So long as the institutions making use of a money market regard a particular type of credit instrument as a reasonably close substitute—that is, treat it as "liquid"—and so long as the central bank acquiesces in or approves of this approach, the instrument is in practice a money market asset. Thus no single definition or list can apply to the money markets of all countries nor will the list remain the same through the years in the money market of any given country.

The buying and selling of currencies

The international money market. Each central bank usually holds some form of reserve that is acceptable in settling international transactions. International monetary reserves are mainly gold, or "money market assets" in some country whose currency is widely used, such as the United States dollar. The monetary laws of all countries provide for the establishment of some kind of parity between their currencies and those of other countries. This parity may be defined either in terms of gold or in relation to a key currency such as the British pound sterling or the United States dollar, which in turn has a fixed parity with gold. A country maintains the "convertibility" of its currency by standing ready to buy and sell gold or other currencies in exchange for its own at prices within a fixed and rather narrow "spread" above or below the "exchange rate" for its own currency that is implied by the declared parity.

Because world trade continually gives rise to various needs for payment in various currencies, an international money market must exist so that traders with an excess of one currency can use it to buy another currency for which they have a need. Within the scope of convertibility arrangements, this trading in currencies is carried out by skilled intermediaries, usually banks or specialized foreign exchange brokers and dealers. Trading in currencies is extensive both for immediate use ("spot") and for future ("forward") delivery. Quotations vary according to changes in supply and demand, over the range between the upper and lower buying and selling prices set by official parity. If no parity has been set quotations may fluctuate widely. If a currency is subject to exchange controls, there may be two or more quotations for different uses of the same nominal currency.

Changes in a country's balance of payments may affect the usefulness or prestige of its currency. A sustained and substantial balance of payments deficit (outpayments larger than inpayments), for example, will result in continuous large increases in the world supply of its currency, possibly leading to some decline in its acceptability abroad and to a loss of international monetary reserves. At the same time, an outward drain may reduce the reserves of the commercial banks (the base for the domestic money supply), unless the central bank takes offsetting action.

Since 1944 most of the countries that have domestic money markets or that play a role in the international money market have been joined together in the International Monetary Fund, which represents a pooling of part of the foreign exchange reserves (including gold) of more than 100 member countries. Drawings on the pool may be made by member countries to meet some of the reserve drains arising from balance of payments deficits and in amounts related to the quota that each has subscribed.

The internal money markets of a surprisingly high proportion of the countries of the world are quite rudimentary. The work of the money market in these countries is done largely by transfers of deposit balances, government securities, or foreign exchange among a few banks and between them and the central bank. But in nearly all such cases there is genuine discontent with the rigidity of these limited facilities and a desire to develop a structure, as well as instruments and procedures, which would provide the open-market attributes of the arrangements that have evolved in the leading countries. Several of the more fully developed money markets are described below.

The Federal Reserve System

The U.S. money market. The domestic money market in the United States carries out the largest volume of transactions of any such market in the world; its participants include the most heterogeneous group of financial and nonfinancial concerns to be found in any money market; it permits trading in an unusually wide variety of money substitutes; and it is less centralized geographically than the money market of any other country. Although there has always been a clustering of money market activities in New York City and much of the country's participation in the international money market centres there, a process of continuous change during the 20th century has produced a genuinely national money market.

By 1935 the financial crises of the Great Depression had resulted in a basic revision of the banking laws. All gold had been withdrawn from internal circulation in 1933 and was henceforth held by the U.S. Treasury for use only in settling net flows of international payments among governments or central banks; its price was raised to $35 per ounce, and the U.S. dollar became the key currency in an international gold bullion standard. Domestically, the changes included legislative recognition of the primary importance of unified open-market operations by the Federal Reserve System and delegation to the board of governors of the Federal Reserve System of authority to raise or lower the ratios required between reserves and commercial bank deposits. Although about half of the 30,000 separate banks existing in the early 1920s had disappeared by the mid-1930s, the essential character of commercial banking in the U.S. remained that of a "unit" (or single-outlet) banking system in contrast to those of most other countries, which had a small number of large branch-banking organizations.

The unit banking system. This system has led inevitably to striking differences between money market arrangements in the United States and those of other countries. At times, some smaller banks almost inevitably find that the wholesale facilities of the money market cannot provide promptly the funds needed to meet unexpected reserve drains, as deposits move about the country from one bank to another. To provide temporary relief, pending a return flow of funds or more gradual disposal of other liquid assets in the money market, such banks have the privilege, if they are members of the Federal Reserve System, of borrowing for reasonable periods at their own Federal Reserve bank. At times some large banks, which serve as depositories for part of the liquid balances of many of the smaller ones (including those that are not members of the Federal Reserve System) also find that demands converging on them are much greater than expected. These large banks, too, can borrow temporarily at a Federal Reserve bank if other money market facilities are not adequate to their needs. Because these borrowing needs are unavoidably frequent in a vast unit banking system and, as a rule, do not indicate poor management, the discount rate charged by the Federal Reserve banks on such borrowing is not ordinarily put at punitive or severe penalty levels—thus, contrary to practice in many other countries, the central bank does not always maintain its interest rate well above those prevailing on marketable money market instruments. To avoid abuse, there is continuous surveillance of the borrowing banks by the Federal Reserve banks.

Along with this practice of borrowing at a Federal Reserve bank has developed the market for "federal funds." This specialized part of the money market provides for the direct transfer to a member bank of balances on the books of a Federal Reserve bank in return for payment of a variable rate of interest called the "federal funds rate." These funds are immediately available. There are transactions, too, in funds that are on deposit at commercial banks—by means of loans between banks, or through loans by one large depositor to another. Because these must be collected through a clearing process, they are usually called "clearinghouse funds."

Money market instruments. Transactions in federal funds and clearinghouse funds are further supplemented by transactions in which either kind of money is exchanged for some other liquid, money market instrument, most frequently government securities. The magnitude of

the market for government securities became so great after World War II that it overshadowed all other elements of the money market. Trading in outstanding "governments" is virtually all done through dealers who buy and sell for their own account at prices which they quote on request (standing ready to "bid" for or to "offer" any outstanding issue). Most of these dealers have head offices located in New York City, but all are engaged in nationwide operations. Their transactions and the lending arrangements through which they finance their own inventories of government securities have evolved into a particularly sensitive indicator of the pressures of supply and demand on the money market from day to day. The most common form of dealer financing is the repurchase agreement, through which dealers sell parts of their inventory temporarily, subject to repurchase.

Closely interrelated, often through trading operations conducted by the same dealers, are the much smaller markets for bank drafts, bills of exchange, and commercial paper. Alongside these other markets and actually somewhat larger in outstanding volume are the markets for securities issued by various "agencies" created by federal statute, such as the Federal Home Loan banks and Federal Land banks. Another money market instrument is the negotiable time certificate of deposit (CD), issued in large volume by commercial banks, which first became significant in 1962. While the owner of a time CD cannot withdraw his deposit before the maturity date initially agreed upon, he can sell it at any time in a secondary market that is conducted by government securities dealers.

Certificates of deposit

The Federal Reserve System conducts day-to-day operations in the money market on its own initiative in order to assist the smooth working of the nation's financial machinery and to exert a general influence aimed at fostering economic growth and limiting economic instability. Its transactions include substantial outright purchases or sales of government securities, relatively small purchases and run-offs of bankers' acceptances, and a considerable volume of loans made for a few days at a time to dealers in government securities or acceptances in the form of repurchase agreements. While it is still the commercial banks as a group that have the greatest continuing need for the combined facilities of the nationwide money market, there is frequent and continuous participation by a great variety of institutional investors who channel the public's savings into various uses and who must always also make some provision for their own liquidity.

Perhaps the most unusual feature in the composition of the U.S. money market is the great importance attained by nonfinancial business concerns and local units of government since World War II. Corporate treasurers and the treasurers of many states and local political subdivisions and authorities have become so keenly sensitive to the profitable possibilities of managing their own liquid holdings instead of relying on the commercial banks as most had done formerly that this group at times provides nearly as large a part of the volatile financing needs of government securities dealers, for example, as comes from the banks. Moreover, banks outside New York City sometimes supply more of the financing needed by these dealers than do the traditional "money market banks" in New York City. The nationwide character of the money market is also shown by the participation of nearly 200 banks in the federal-funds market—banks that are widely scattered among all Federal Reserve districts, although the bulk of all transactions is executed through facilities located in New York.

While the U.S. money market has become truly national, it still needs a final clearing centre upon which the net impact of changes in overall supply or demand can ultimately converge and where the final balancing adjustments of the market as a whole can be accomplished. In filling that need, New York City continues to be the centre of the national money market.

The British money market. *The discount houses.* In Great Britain the money market consists of a number of linked markets, all of them concentrated in London. The 12 specialist banks known as discount houses have the longest history as money market institutions; they have their origin in the London bill broker who in the early 19th century made the market in inland commercial bills. By selling bills through this market, the growing industrial and urban areas were able to draw upon the surplus savings of the agricultural areas. Quite early many bill brokers began to borrow money from banks in order to buy and hold these bills, instead of simply acting as brokers, and thus became the first discount houses. Since then the major assets held by the discount houses have at different times been commercial bills (first inland bills as described above and later bills financing international trade), treasury bills, and short-dated government bonds. During the 1960s there was a resurgence of the commercial bill, which finally became the discount houses' largest single class of asset, only to be overtaken later by the certificate of deposit.

Important changes were introduced into the British monetary system in 1971, but money at call with the discount houses retained its role as a reserve asset. Such is the safety and liquidity of call money that, despite the fractionally lower rate on it compared with other reserve assets, the banks hold about half of their required reserves in this form. This in turn provides the discount houses with a large pool of funds, which they invest in relatively short-dated assets, of which the most important is sterling certificates of deposit, followed by commercial bills, local authority securities, and treasury bills. This pattern of assets is greatly influenced by the fact that all call loans to the discount houses are secured loans, parcels of assets being deposited *pro rata* with the lending banks as security, and the assets held by the discount houses must therefore be suitable for use as such security.

They also need to hold a substantial proportion of assets that are rediscountable at the Bank of England in case of need, and the Bank of England limits their holding of assets other than public sector debt to a maximum of 20 times their capital resources.

Operations in money

On the liabilities side of the discount house's balance sheet, operating in call money is part of its day-to-day work. A bank that expects to make net payments to other banks during the day (for example, in settlement of checks paid by its customers to their customers) will probably call in some of its call loans, and by convention this is done before noon. Since the banks that have called in money then pay it to other banks, these other banks will have an equal amount to re-lend to the discount houses in the afternoon. Thus the discount houses can "balance their books"—borrow enough money in the afternoon to replace the loans called from them in the morning.

It is not uncommon for perhaps £100,000,000 to be called from, and re-lent to, the discount houses on an active day.

There is one main reason why the money position may not balance in this way. The British government accounts are kept with the Bank of England, which does not lend at call as other banks do. Thus net payments into or out of these government accounts will cause a net shortage or surplus of money for the discount houses in the afternoon and will tend to cause money rates to rise or fall. The Bank of England can allow such shortages or surpluses to affect interest rates, or it can offset them by buying or selling bills or by lending overnight to the discount houses at market rates. Even if the Bank of England does not act in this way to meet a shortage of funds, the discount houses are always finally able to secure the funds they need by their right to borrow from the Bank of England (the lender of last resort) against approved security at the "minimum lending rate" (the penalty rate).

Dealing in assets

On the assets side of their balance sheets, the discount houses are active dealers in a number of the assets they hold. They make the market in sterling certificates of deposit and in commercial bills, quoting buying and selling rates for different maturities. They also quote selling rates for treasury bills that they acquire at the weekly tender in competition with each other and with any other banks that may tender, including the Bank of England. Most of these other banks tender for treasury bills in order to hold them to maturity, but the discount houses sell theirs on the average when only a few weeks of the bills' 91-day life has passed. A large proportion of these bills is sold to the

clearing banks, which do not tender on their own account.

The Bank of England minimum lending rate is normally determined for each week 0.5–0.75 percent above the average treasury bill rate at the previous Friday's tender. The bank, however, has the power to fix it at a different level if it so wishes, and this has been done.

Other markets. Important changes have also occurred outside the discount market described above; after the mid-1950s there was steady growth in public borrowing by local authorities. This led to an active local authority loan market conducted through a number of brokers, where money can be lent on deposit for a range of maturities from two days up to a year (and indeed for longer periods). Much more rapid was the growth after the mid-1960s of the interbank market, in which banks borrow and lend unsecured for a range of maturities from overnight upward. This market also is conducted through brokers, often firms that also operate in the local authority and other markets; a number of these firms of brokers are subsidiaries of discount houses.

In addition to the markets mentioned, there is the gilt-edged (government bond) market on the stock exchange; short-dated bonds are held by the discount houses and by banks and other money market participants, as are short-dated local authority stocks and local authority "yearling" (very short-dated) bonds. With flexibility of bank deposit rates (at least for deposits of large denomination), both banks and nonbank transactors are faced with a wide and competitive range of sterling money market facilities in London.

Finally, mention should be made of the Eurodollar market, because London is its centre; this is an entrepôt market with a very large volume of business in U.S. dollar balances, conducted through brokers (often the same firms that operate in the sterling markets), and U.K. banks are active participants. However, owing to exchange control there has been little significant interaction between the Eurodollar market and the U.K. domestic money market.

The money markets of other countries. *The Canadian money market.* The Canadian money market was substantially broadened in 1954 with the introduction of day-to-day bank loans against Government of Canada treasury bills and other short-term government and government-guaranteed securities. Treasury bills of 91 days' and 182 days' maturity are issued weekly with the occasional offering of a longer maturity of up to one year. Government of Canada bonds and Government of Canada guaranteed bonds are issued at less regular intervals.

Government of Canada bonds

Groups involved in the money market are the following: the government, as the issuer of the securities; the Bank of Canada, acting as issuing agent for the government and as a large holder of market material; the chartered banks, as large holders and as distributors and potential buyers and sellers of bills and bonds at all times; the security dealers, as carriers of inventories and traders in such securities; and the public (mainly provincial and municipal governments and larger corporations), as short-term investors.

Treasury bills are sold by competitive tender in which the Bank of Canada, the chartered banks, and a small number of investment dealers participate. Bonds are normally issued at a price at which the yield is in line with outstanding comparable issues.

The central bank, through its tender at the weekly treasury-bill sale, active manipulation of its own bill and bond portfolio, and regulation of the money supply, has workable instruments for active monetary control. For both banks and qualified dealers, the Bank of Canada acts as lender of last resort. The rate is set slightly above the average rate of the last treasury bill auction to discourage regular borrowing.

The German money market. In what was formerly West Germany, where the money market developed strongly after World War II, transactions have been to a large extent confined to interbank loans. In addition, insurance companies and other nonbank investors are also important lenders of short-term funds. Treasury bills and other short-term bills and notes from government agencies (railways and post) were gaining in importance by the 1960s, whereas in 1955 certain nonmarketable securities (the so-called equalization claims, created during the 1948 currency reform) held by the Bundesbank were transformed into short-term marketable securities in order to obtain suitable market material for the open-market operations of the Bundesbank. Banks are not used to dealing in short-term government securities between each other. They generally either hold these securities to maturity or resell them to the central bank at its buying rates, so that a true money market has not developed.

The market for commercial paper is of some significance, and dealing in it takes place from time to time between banks, especially in times of tight market conditions. Comprehensive regulations have been given through the Bundesbank about the rediscountability of the several kinds of commercial paper.

The influence of the Bundesbank on the monetary situation through open-market operations by the 1960s was greatly hampered by the vast liquidity of the banking system as a consequence of the persistence of Germany's favourable balance of payments situation.

The French money market. The French money market is fairly well established, but its size is restricted by the fact that in France currency still plays an important role in the money supply, whereas by regulations the nonfinancial private sector of the economy is excluded from dealing in the market. Banks as well as a few public or semipublic agencies working in the financial sphere and intermediaries—brokers and discount houses—constitute the market. Transactions take place in commercial paper and in treasury bills. The monetary authorities maintain a special bookkeeping system for all the treasury bills held by banks and other financial institutions, under which such bills are not represented by actual certificates but by entries in special accounts administered by the Banque de France for the treasury.

The central bank's open-market operations, which were normally limited to smoothing out disturbances in the local money market, have gained importance in recent years. Open-market transactions are effected to keep domestic money market rates in line with international rates, in an effort to prevent unwanted capital flows. The possibilities of the central bank's influencing the monetary situation through the money market are limited to the large government needs for short-term funds, no market for long-term government borrowing being established.

The Japanese money market. In Japan's rapidly growing economy the demand for funds, both short-term and long-term, has been persistently strong. Commercial banks and other financial institutions have therefore had an important role. The monetary authorities (the Ministry of Finance and the Bank of Japan) have been unwilling to allow market forces to equilibrate demand and supply in many financial markets for fear that interest rates would become excessively high. Most interest rates have been set administratively at levels high by international comparison (until the late 1960s) but lower than market forces would have dictated. Monetary policy is implemented by controls on both the availability of credit and its cost.

Under these circumstances, Japan has had a very restricted money market. The market for short-term government securities is negligible; the low, pegged interest rate means that the Bank of Japan is the main buyer and that open-market operations are impossible. Transactions in commercial paper are minimal, being discouraged because they would tend to undermine the structure of interest rates and financial institutions.

Call money market in Japan

Only the call money market is well developed. It is restricted to transactions among financial institutions. The interest rate on call money has been relatively free, and persistently above most other short-term and long-term rates. Although small amounts are lent overnight, most are "unconditional loans" (repayment after one day's notice, with a minimum of two days) or "over-month-end-loans" (repayment on a fixed day the following month). The pattern of flows is rather stable, despite seasonal and cyclical fluctuations. City banks are the major borrowers; they have a strong demand for loans by large enterprises and use call funds as a major source of liquidity. Major lenders are local banks, trust banks, credit associations,

and agricultural cooperatives, which collect individual urban and rural savings and are attracted by the high yields, liquidity, and low risk of call loans relative to other uses. Call brokers help make a market, though most funds flow directly from one financial institution to another. About three-quarters of the funds flow through the Tokyo market, and there are also call markets in Ōsaka and Nagoya.

Money markets in developing countries. Well-developed money markets exist in only a few high-income countries. In other countries money markets are narrow, poorly integrated, and in many cases virtually nonexistent. Despite the many differences among countries, one can say in general that the degree of development of a country's financial system, including its money markets, is directly related to the level of its economy. Most very-low-income countries have limited financial systems in which money markets play no role. In many former colonies, notably in Africa, expatriate commercial banks had substituted for a local money market; the banks met fluctuations in loan demand by changing their balances at head offices in London or elsewhere. More recently, government policies have encouraged these banks to develop domestic channels for temporary surpluses and deficits. Persistent inflation has been another factor inhibiting the growth of money markets in developing countries, notably in Latin America.

Most developing countries, except those having socialist systems, have the encouragement of money markets as a policy objective, if only to provide outlets for short-term government securities. At the same time many of these governments pursue low-interest-rate policies in order to reduce the cost of government debt and to encourage investment. Such policies discourage saving and make money market instruments unattractive. Nevertheless, a demand for short-term funds and a supply of them exist in all market-oriented economies. In many developing countries these pressures have led to "unorganized money markets," which are often highly developed in urban areas. Such markets are unorganized because they are outside "normal" financial institutions; they manage to escape government controls over interest rates; but at the same time they do not function very effectively because interest rates are high and contacts between localities and among borrowers and lenders are limited. In all developing countries traditional forms of moneylending continue, particularly for agriculture and small enterprise.

(H.T.P./R.V.R./R.F.G.A./C.G.)

The markets and social welfare

The branch of academic teaching called the "economics of welfare" is nowadays generally expounded by starting with a presumption in favour of laissez-faire and free competition and then following it by a list of reservations and exceptions that destroy its validity. One is first asked to imagine a particular group of individuals, each with his tastes for a predetermined list of specific commodities, with a predetermined endowment of labour power, with specified equipment and stocks, and with a given body of technical knowledge. These individuals can produce various alternative combinations of commodities. If resources were fully utilized, it would be impossible to produce more of any one commodity without producing less of others. One could then speak of an "opportunity cost" of each commodity—that is, the cost of producing a little more of it in terms of the amounts of other commodities that would have to be sacrificed.

Static balance of interests

On the other side of the market, the same individuals appear as consumers. If their tastes are all alike, it can be argued that there is one set of outputs and prices at which the relative subjective valuations are proportional to relative opportunity costs. This situation is the optimum in the sense that any move away from it would reduce the total satisfaction. The argument is not so simple when different consumers have different tastes. At any one pattern of prices established in the market (with full utilization of resources), each consumer can adjust his purchases so as to maximize his satisfaction at those prices. Then, starting from that set of prices, it can be shown that no one consumer could be made better off, by changing the composition of output, without making some other worse off. This is a powerful argument for the status quo, wherever it may happen to be. At every other point, there would be a different status quo, with a pattern of prices suiting some consumers better and some worse than the one that was chosen at the beginning of the argument.

The first general objection that is now admitted to this scheme (over and above some technical points within its own terms) it that is is purely static. Actual life is lived in the stream of time. In any economy, tastes, commodities, resources, and technology are continuously changing and modifying each other.

Second, there is a deep-seated inconsistency in the assumptions: when every individual pursues his own advantage, atomistic competition cannot persist, for any group of sellers or of buyers can gain by acting together and sharing the benefits among individual members of the group. Perfect competition, like free trade among nations, can persist only when there is some rule of behaviour that overrides pure self-interest.

Third, it is necessary to consider the distribution of consumption between individuals who make up the market. The purchasing power of each is limited by the receipts that he draws from his sales. His receipts depend on the amount of his original endowment and the price of the product he offers to sell. It is obvious that the distribution of the benefits of the market between individuals is quite arbitrary, and the market optimum is therefore not the same as their welfare optimum. When this objection to the laissez-faire principle is admitted, it is often suggested that inequalities might be corrected by a system of bounties and taxes; but this has never been taken seriously as a practical scheme.

A fourth set of objections comes under the heading of differences between private and social costs. The classic example is the smoke nuisance, which imposes costs upon the public that the factory concerned cannot be charged for. Examples of this phenomenon on a devastating scale are now daily coming to notice. At the same time there are many socially beneficial activities for which it is impossible to collect adequate payment from individuals in a society of unequal wealth and income—not only performances of grand opera but the whole of education and the health service.

Thus the doctrine that the free play of individual interests in a competitive market maximizes welfare for society as a whole has been demolished by its own exponents. Yet these notions still have an important influence on the formation of ideology. The rationalization grew out of the 19th-century utilitarian philosophers' hedonistic calculus, which regarded all human life as governed by the pursuit of pleasure and avoidance of pain. This train of thought identifies pleasure with consumption, leaving out of account the whole sphere of conditions in which work is carried on, and finally it sees consumption in terms of spending money. The whole economic basis of life is thus reduced to terms of commercial transactions. As the American critic Thorstein Veblen pointed out,

> so great and pervading a force has this habit of pecuniary accountancy become that it extends, often as a matter of course, to many facts which properly have no pecuniary bearing and no pecuniary magnitude, as, for example, works of art, science, scholarship, and religion.

THE POLITICS OF THE MARKET

The doctrines of laissez-faire are attractive in many ways. If the economy is a self-regulating mechanism and if economics is a system of scientific laws, then moral and political problems are excluded. Questions of social justice do not arise. The function of government is to be strictly neutral between interested parties. But when people come to recognize that the market, by its very nature, is necessarily a scene of conflicting interests, every element in it becomes a moral and political problem. This is distressing because one can no longer rely upon "principles of economics" to provide safe and simple rules for finding the correct solutions.

Laissez-faire as an ideal

The intrusion of politics into economic affairs increased dramatically in all the Western industrial nations after

1945. Capitalism took on a new shape, with certain characteristics that distinguish it from all former systems. The reasons for this mutation in the free market economy are numerous. Perhaps the most important was the experience of the great slump of the 1930s. After the war, public opinion, business interests, politicians, and administrators were united in resolving that massive unemployment must not be allowed to recur. Indeed, those who earlier had been the strongest adherents of laissez-faire became the strongest supporters of policies to maintain full employment, arguing that this is the best way to preserve the free enterprise system. Some observers of modern capitalism have maintained that the real purpose of the full-employment policy is to maintain profitability for the great corporations, but it cannot be denied that the results are important for all classes.

The traditional doctrines of the economists are still influential. Even John Maynard Keynes, whose critique of the traditional economics had so much to do with creating the new, gave his blessing to the old conception of the free market. He argued that, if our central controls succeed in establishing full employment, there is no objection to be raised against the orthodox theory of the manner in which private self-interest will determine what in particular is produced, or how the value of the final product will be distributed.

Evidently this view owes more to sentiment than to logic. It is impossible to have a policy designed to maintain effective demand in the abstract. Every policy must have some concrete content. The instruments in the hands of government—monetary policy, the exchange rate, taxation, government expenditure—impinge in specific ways upon specific interests. Taxation may be designed to foster either investment or consumption; if the latter, it may be done either by adhering to the principle of "to him that hath shall be given" (that is, by a proportional reduction in direct tax rates) or by favouring lower-income groups. Government investment cannot be neutral either; there is no criterion for allocating funds in a neutral manner between, say, armaments and hospitals.

While economic affairs grow ever more overtly political, at the same time commercial influences spread into new spheres. Old notions of loyalty, service, and proper behaviour are undermined by commercial principles. Continuous inflation and rapid technical change make it necessary for every group to defend itself against the erosion of its relative income and status. It would appear that the new capitalism, for all its benefits, may have been developing internal contradictions of its own that threaten its future stability.

Meanwhile, many of the new and developing nations find that the opening up of their resources and their markets turns out to be more advantageous for established businesses based on successful capitalist industry than for struggling newcomers in their own countries. The economic performance of the so-called developing countries does not give much support to the doctrine that the free play of market forces can be relied upon to maximize human welfare. (J.Ro./Ed.)

BIBLIOGRAPHY

General works. GLENN G. MUNN, F.L. GARCIA, and CHARLES J. WOELFEL, *Encyclopedia of Banking and Finance*, 9th ed., rev. and expanded (also published as *The St. James Encyclopedia of Banking & Finance*, 1991), provides comprehensive definitions, many with bibliographies. EDWARD I. ALTMAN and MARY JANE MCKINNEY (eds.), *Handbook of Financial Markets and Institutions*, 6th ed. (1987), is a thorough compilation. Detailed information on a variety of markets is provided in FRANCIS A. LEES and MAXIMO ENG, *International Financial Markets: Development of the Present System and Future Prospects* (1975), a descriptive treatment; CHARLES R. GEISST, *A Guide to the Financial Markets*, 2nd ed. (1989), for the general reader; FRANK J. FABOZZI and FRANK G. ZARB, *Handbook of Financial Markets: Securities, Options, and Futures*, 2nd ed. (1986); and PERRY J. KAUFMAN, *Handbook of Futures Markets: Commodity, Financial, Stock Index, and Options* (1984), including the history, regulation, and mechanics of futures trading. Further discussion of financial futures is found in MARK J. POWERS and MARK G. CASTELINO, *Inside the Financial Futures Markets*, 3rd ed. (1991), an explanation of the exchanges and their functions; and NANCY H. ROTHSTEIN and JAMES M. LITTLE (eds.), *The Handbook of Financial Futures: A Guide for Investors and Professional Financial Managers* (1984), a discussion of the market's development, organization, and regulation.

The market in economic doctrine and history. The first chapter of ADAM SMITH, *An Inquiry into the Nature and Causes of the Wealth of Nations* (1776, reprinted frequently), contains his famous discussion of the division of labour. ALFRED MARSHALL, *Principles of Economics*, 9th ed., 2 vol. (1961), conveys his approach to the market. The development of the general equilibrium approach to markets by Leon Walrus and others is well recounted by JOSEPH A. SCHUMPETER, *A History of Economic Analysis*, ed. by ELIZABETH BOODY SCHUMPETER (1954). The best short introduction to the Keynesian Revolution is by MICHAL KALECKI, *Studies in the Theory of Business Cycles, 1933–1939* (1966; originally published in Polish, 1962). These essays were written before the publication of the great work of JOHN MAYNARD KEYNES, *The General Theory of Employment, Interest, and Money* (1935, reissued 1991). A critical account of the theory of imperfect competition is presented in the preface to JOAN ROBINSON, *The Economics of Imperfect Competition*, 2nd ed. (1969, reissued 1976). A slightly different approach is that of EDWARD HASTINGS CHAMBERLIN, *The Theory of Monopolistic Competition*, 8th ed. (1962). Economies without markets are described in KARL POLANYI, *Primitive, Archaic, and Modern Economies*, ed. by GEORGE DALTON (1968), a collection of essays of great interest and originality. ANDREW SHONFIELD, *Modern Capitalism* (1965, reissued 1978), studies the ways in which various countries have adapted their economic administration to modern requirements. A more critical view of modern capitalism is that of JOHN KENNETH GALBRAITH, *The New Industrial State*, 4th ed. (1985). A Marxist view is set forth by PAUL BARAN and PAUL SWEEZY, *Monopoly Capital* (1966). A summary of the attempts at economic reform in the then-existent Soviet Union and other countries with socialist economies is given in MICHAEL ELLMAN, *Economic Reform in the Soviet Union* (1969). The economic problems of the poor countries are examined in GUNNAR MYRDAL, *The Challenge of World Poverty* (1970), a continuation of his monumental work *Asian Drama: An Inquiry into the Poverty of Nations*, 3 vol. (1968), also available in an abridged edition (1971).

Commodity and futures markets. J.R. HICKS, *Value and Capital*, 2nd ed. (1946, reissued 1975), contains a short discussion of the theory of "normal backwardation," also known as the Keynes-Hicks hypothesis. HOLBROOK WORKING, "New Concepts Concerning Futures, Markets, and Prices," *American Economic Review*, 52(1):431–459 (June 1962), presents his theories on the role of hedging and the functions of futures markets. The instability of markets for primary commodities is the theme of the Argentinian economist RAUL PREBISCH, *Towards a New Trade Policy for Development* (1964). Recent work on the specific methods and rules of the major world exchanges is included in JOHN BUCKLEY (ed.), *Guide to World Commodity Markets*, 5th ed. (1986). Basic works on commodity futures trading include GERALD GOLD, *Modern Commodity Futures Trading*, 7th rev. ed. (1975); and BRUCE G. GOULD, *The Dow Jones-Irwin Guide to Commodities Trading*, rev. ed. (1981). See also BARRY P. BOSWORTH and ROBERT Z. LAWRENCE, *Commodity Prices and the New Inflation* (1982), comparing the experiences of the United States, West Germany, and Japan, and offering policy proposals; and ROBERT L. ROTHSTEIN, *Global Bargaining* (1979), utilizing the 1974–77 United Nations conference on trade and development negotiations to develop an international commodity policy. An extensive summary of work on commodity futures trading is provided by JAMES B. WOY, *Commodity Futures Trading: A Bibliographic Guide* (1976).

Securities trading. *The Spicer & Oppenheim Guide to Securities Markets Around the World* (1988); and PAUL STONHAM, *Major Stock Markets of Europe* (1982), are good general surveys of world stock exchanges. ROBERT SOBEL, *N.Y.S.E.: A History of the New York Stock Exchange, 1935–1975* (1975), is a readable survey of this important exchange. See also JOEL SELIGMAN, *The Transformation of Wall Street: A History of the Securities and Exchange Commission and Modern Corporate Finance* (1982). Reference manuals include RICHARD J. TEWELES and EDWARD S. BRADLEY, *The Stock Market*, 5th ed. (1987); and FRANK G. ZARB and GABRIEL T. KEREKES (eds.), *The Stock Market Handbook* (1970). WILLIAM J. BAUMOL, *The Stock Market and Economic Efficiency* (1965), is an interesting effort to apply economic theory to the securities market. ARTHUR STONE DEWING, *The Financial Policy of Corporations*, 2 vol., 5th ed. (1953), is a classic treatise on financial policy, particularly useful for historical and statistical purposes. HUGH BULLOCK, *The Story of Investment Companies* (1959), recounts the development of mutual funds. VINCENT P. CAROSSO, *Investment Banking in America* (1970), provides a relatively thorough history. JOHN W. HAZARD and MILTON CHRISTIE, *The Investment Business* (1964), readably condenses the landmark

U.S. Securities and Exchange Commission's special study of the securities markets. Investment texts include HARRY C. SAUVAIN, *Investment Management*, 4th ed. (1973); and JEROME B. COHEN, EDWARD D. ZINBARG, and ARTHUR ZEIKEL, *Investment Analysis and Portfolio Management*, 5th ed. (1987), a comprehensive work. *Graham and Dodd's Security Analysis*, 5th ed. by SIDNEY COTTLE, ROGER F. MURRAY, and FRANK E. BLOCK (1988), is a classic work that led to the development of the field of security analysis. RICHARD W. JENNINGS, HAROLD MARSH, JR., and JOHN C. COFFEE, JR. (eds.), *Securities Regulation*, 7th ed. (1992), is a leading textbook dealing with the legal background of securities regulation. LOUIS LOSS and JOEL SELIGMAN, *Securities Regulation*, 3rd ed. (1989–), is a classic work kept up-to-date with supplements that delves into all aspects of the U.S. federal regulation of securities and securities markets.

Money market. The development and operation of the international capital market is addressed by M.S. MENDELSOHN, *Money on the Move: The Modern International Capital Market* (1980). Reference works include MARCIA STIGUM, *The Money Market*, 3rd ed. (1990), comprehensive and readable; and GUNTER DUFEY and IAN H. GIDDY, *The International Money Market* (1978). TIMOTHY Q. COOK and TIMOTHY D. ROWE (eds.), *Instruments of the Money Market*, 6th ed. (1986), explains such key instruments as Eurodollars, treasury securities, and federal funds. DAVID M. DARST, *The Handbook of the Bond and Money Markets* (1981), is a practical guide. Money markets in countries in Asia and the Pacific are studied by ARON VINER, *Inside Japanese Financial Markets* (1988); YOSHIO SUZUKI, *Money and Banking in Contemporary Japan*, trans. from the Japanese (1980), analyzing Japan's participation in international capital markets; *The Japanese Financial System* (1978), published by the Bank of Japan, a brief description of financial institutions, financial markets, and characteristics of the financial structure; and MICHAEL T. SKULLY (ed.), *Financial Institutions and Markets in the Far East* (1982), *Financial Institutions and Markets in Southeast Asia* (1984), *Financial Institutions and Markets in the Southwest Pacific* (1985), and *Financial Institutions and Markets in the South Pacific* (1987).

The markets and social welfare. The classic appraisal of the market from the standpoint of social welfare is A.C. PIGOU, *The Economics of Welfare*, 4th ed. (1962). Appraisals of welfare economics include I.M.D. LITTLE, *A Critique of Welfare Economics*, 2nd ed. (1957, reissued 1970); J. de V. GRAAFF, *Theoretical Welfare Economics* (1957, reissued 1975); and MAURICE DOBB, *On Economic Theory and Socialism* (1955, reissued 1972). THORSTEIN VEBLEN, *The Place of Science in Modern Civilisation, and Other Essays* (1919, reprinted 1990), most directly expresses his critique of the market ideology. (Ed.)

Marseille

Founded more than 2,500 years ago, the port city of Marseille (English conventional spelling Marseilles) has a history of vigorous independence asserted against central authority in a variety of forms. It retained its status as a free city even after falling to Julius Caesar's troops in the 1st century BC, and after centuries of decline it was revived and allowed great independence under the local control of the viscounts of Provence in the 10th–14th centuries. After Provence joined the Kingdom of France in the 15th century, Marseille retained a separate administration and continually engaged in spirited revolt against kings or governments that threatened its liberties. It was for this reason that in 1800, when France was divided into the present administrative *départements,* Marseille was only reluctantly granted its status as capital of the Bouches-du-Rhône.

Frenchmen elsewhere, convinced that the Mediterranean climes of Provence could never be fully integrated into either the French realm or the Gallic spirit, long looked upon Marseille as a sort of folkloric institution: a place of comic anecdote and dialect, with a seasoning of picturesque criminality; a place where the citizens played a peculiar form of outdoor bowling known as *pétanque,* concocted the glorious garlic- and saffron-flavoured fish stew known as bouillabaisse, and consumed rich, savory, absinthe-like Provençal pastis.

By whatever proportion fact may have been coloured with myth in its image, Marseille undoubtedly forms a major element in the economic and social structure of France. With Aix-en-Provence it forms the second largest urban agglomeration in France, and in association with the outport of Fos-sur-Mer, about 23 miles (37 kilometres) to the northwest, it is the country's largest seaport. Under the Socialist mayor Gaston Defferre, whose administration, from 1953 until his death in 1986, was the longest in its history, Marseille experienced major transformation—a process that is still continuing.

Marseille remains the capital of the Bouches-du-Rhône *département* and is also the administrative and commercial capital of Provence-Alpes-Côte d'Azur, one of France's fastest growing *régions.* It is situated on the Mediterranean's Gulf of Lion within a semicircle of limestone hills and lies 536 miles south-southeast of Paris by rail and 218 miles southeast of Lyon. The city proper has an area of about 93 square miles (241 square kilometres), and the metropolitan area covers some 365 square miles (946 square kilometres).

This article is divided into the following sections:

Physical and human geography

The character of Marseille has been determined to a great extent by geographic location. Its natural harbour, sheltered by a semicircle of hills and close to the estuary of the Rhône River, offered its first settlers the prospect of linking the Mediterranean seaways with northern Europe across a land that, in classical times, was made largely impassable by forests. The trading port founded by Greeks from the city of Phocaea in about 600 BC was to attract both settlers and visitors. The first of these account for a heterogeneous population and the second for services designed to cater to seamen and merchants. Marseille has the oldest chamber of commerce in France, established in 1599. It is a city of mosques and synagogues, besides many varieties of Christian churches. Its bars and brothels have been a magnet for dishonest dealings, and its waterfront still evokes the romance of a gateway to distant lands.

The city's most enduring characteristic, however, has been its readiness to welcome change. Its architecture preserves few vestiges of the past. Some landmarks, such as the transporter bridge that crossed the Old Port and the Panier district north of the harbour, were destroyed by the German occupation forces in 1943 and 1944. But more change has been wrought by the Marseillais themselves. Despite the legend that attaches to them, they are an unsentimental people open to new ideas.

For centuries, Marseille's mixed population and its inclination to political dissidence had made the city seem both foreign and marginal to French life and culture. After World War II, however, it was able to develop as a major European port and industrial centre. The city that had been the starting point for past colonial enterprises bore a large share of the aftermath of French colonialism. It proved remarkably successful in absorbing new waves of immigrants, notably the former European colonists who crossed the Mediterranean from North Africa after Algeria won its independence in 1962. The building of the industrial complex at Fos-sur-Mer also attracted many thousands of migrant workers from North Africa in the 1960s, posing further problems of housing the city's immigrant population. Since this period, demographic growth has slowed. However, successive economic crises since the 1970s, combined with major restructuring by large industrial groups, have created a persistent unemployment, particularly among immigrants. This situation has been aggravated by racial hostility toward immigrants and by their marked concentration in particular districts of the city, especially certain northern suburbs. In an attempt to resolve such problems, these areas have become priority targets for the government's urban rehabilitation programs.

THE LANDSCAPE

The city site. Marseille lies in a sheltered depression surrounded by hills, which have inhibited the development of suburbs. The Old Port (Vieux-Port) is a natural harbour and one of the most westerly of the inlets along the rocky coastline characteristic of the northeastern Mediterranean; farther west, beyond the large tidal lake called the Berre Lagoon (Étang de Berre), the shoreline flattens out. There the sandy dunes of the Gulf of Fos and the Camargue region in the Rhône's delta were less attractive to early mariners and were only later seen as offering possibilities for development.

The Old Port

Marseille's natural port was extended in Roman times and again from the 16th century onward to accommodate increased traffic and larger ships. By the 19th century the Old Port was insufficient. An artificial basin at La Joliette, built on the bay just outside of the Old Port, began operation in the mid-1840s, and five additional basins were subsequently built along a five-mile stretch of the bay. Further expansion was also undertaken to the west of the city, with the creation in 1863 of Port-Saint-Louis-du-Rhône. Eventually, in 1965, work began on the development of the port complex at Fos-sur-Mer. The port opened in 1968, and work on the accompanying industrial estate continued into the 1970s.

Marseille's hinterland consists of a chain of mountains, known as the Étoile Chain, which leads northward toward Aix-en-Provence (formerly Marseille's rival as capital of the region) and to Mount Sainte-Victoire. The slopes around Aix are devoted to vineyards, which produce the wines of the Côtes de Provence ("Hills of Provence"). The Étoile Chain has put a limit on the northward expansion of the city, with the result that development has "leapfrogged" this natural barrier in favour of the eastern shores of the Berre Lagoon, around the suburbs of Marignane and Vitrolles. The eastern boundaries of the city also have been extended outward by the pressures of urban growth, particularly along the line of the Huveaune valley.

Climate. The climate of Marseille is not typical of the Mediterranean region as a whole. The lowest rainfall and highest temperatures are found in the hot, dry months of summer, but rainfall reaches a peak in spring and autumn, rather than in winter. The coldest months are December and January, when there is some frost, but otherwise the winter is mild. During the summer months the temperature rises to levels that would be unpleasant were it not for the sea breeze. In winter, Marseille is particularly subject to the dry, cold northwest wind known as the Mistral, which blows down the Rhône Valley, at times with considerable force.

The city layout. The popular area of Marseille was the seedy district, north of the Old Port, known as the Panier, which was destroyed in 1943. The more prosperous middle-class districts developed in the 19th century to the south around the rue Paradis and the avenue du Prado. The period following World War II saw various schemes to develop the city, including the Unité d'Habitation, an 18-story residential block that expressed the architect Le Corbusier's ideal of urban family lodging. The block was intended, when completed in 1952, to be one of six such units; it is now surrounded by luxury apartment buildings. Less attractive are the high-rise, working-class housing blocks developed after 1960, which have come to house a large number of immigrant families. Since the 1970s the municipal authorities have undertaken a massive program of rebuilding in various parts of the city, restoring some of the Panier and turning the district around the Old Port into a largely pedestrian area. The area to the north of the Old Port, extending eastward toward the main railway station (Gare Saint-Charles), is the focus of a major program of urban renewal known as the Euroméditerranée, designed to refurbish existing buildings, provide new housing and office floor space, and create a new university site.

From the historic centre of Marseille at the Old Port, the thoroughfare of La Canebière climbs eastward up the hill; its name is a corruption of a Latin word for hemp, recalling Marseille's importance as a source of hemp and supplier of hemp rope in the Middle Ages. Thronged by people from around the world, La Canebière is the best-known commercial street in Marseille. Its starting point is marked by one of the most imposing public buildings in the city, the Bourse, which houses the Chamber of Commerce and a maritime museum.

The Bourse

Behind the Bourse, building operations in 1967 for a new retail and office complex uncovered a section of the Hellenistic ramparts of Massalia. Excavated by archaeologists, the site, dating from the 3rd and 2nd centuries BC, was found to consist of walls and towers and three sections of Roman road. The ancient port was also excavated. Nearby, close to City Hall on the edge of the port, is the Museum of Roman Warehouses (Musée des Docks Romains), which displays storage jars and other remains of commerce under Roman domination and traces the subsequent history of the port.

The port entrance is guarded by the Fort Saint-Jean, a 13th-century command post of the Knights Hospitaller of St. John of Jerusalem; some ruins remain, along with a tower built in the mid-15th century by King René of

The Old Port and the sanctuary of Notre-Dame-de-la-Garde (centre), Marseille.

Provence. The extant fortress, dating from the 17th century, was part of a nationwide system of defenses. The other side of the harbour entrance is occupied by Fort Saint-Nicolas. In the harbour itself lie the Frioul Islands, on which the city has developed a large centre for water sports. Between these islands and the mainland is the Château d'If, a fortified island where Alexandre Dumas's fictional count of Monte Cristo and large numbers of all-too-real political prisoners were incarcerated.

Other historic buildings are located around the Old Port. In the Place de la Major, the old cathedral of la Major, built on the ruins of a temple of Diana, dates from the 11th century; it was partially dismantled to make way for the eight-domed structure that in 1852 replaced it as the city's cathedral. The dome and supporting arches of the old cathedral are fine examples of Provençal Romanesque stonemasonry.

Old Charity Hospital

Nearby is the Old Charity Hospital (Hospice de la Vieille Charité), built between 1660 and 1750. The interior courtyard surrounds a chapel by Pierre Puget, regarded as the most powerful of French Baroque sculptors. Close by is the Hôtel Dieu, the oldest hospital in the city, built at the end of the 16th century. The principal building, by Jules Hardouin-Mansart, was erected 200 years later and still serves its original function. Almost next door, the bell tower of the vanished church of Accoules, a 14th-century spire mounted on a 12th-century tower, marks the centre of Old Marseille.

On the opposite side of the port stands the crenellated, square-towered basilica of Saint-Victor, dating from the 11th to the 14th century; it once was attached to an abbey founded about 413 by St. John Cassian to commemorate a 3rd-century martyr and patron saint of sailors and millers. When Saint-Victor was built, the abbey was a temporal power of considerable extent, ruling properties in Spain, Sardinia, and the hinterlands of France.

High on the hill over the south side of the Old Port stands the celebrated Notre-Dame-de-la-Garde, a sanctuary honoured from the 8th century. Its present structure was built in 1853–64; its steeple, crowned by a 30-foot (nine-metre) gilded statue of the Virgin, rises 150 feet over the hillside.

THE PEOPLE

Marseille's population, drawn from all parts of the Mediterranean and from elsewhere in Europe and Africa, has always been mixed, so that it has never been possible to talk of a "typical" Marseillais. In 1880, for example, more than one in six of the inhabitants of the city was foreign. New residents have created a diverse pattern, sometimes concentrated in certain districts, such as the Muslim quarter that grew up during the 1970s north of La Canebière, and sometimes specializing in particular trades or professions. Certain groups—Jews, Greeks, Armenians—have their own community leaderships, which have semiofficial recognition.

Former colonials have had a strong impact on the community, and Marseille has always attracted Corsicans (including the Bonaparte family during the French Revolution). Manual labour is increasingly performed by North Africans or Africans who arrive from former colonies. There are marked social contrasts within the city. La Canebière forms an approximate dividing line between the working-class, often run-down areas of the north and the more affluent and salubrious districts of the south.

THE ECONOMY

Industry. Marseille itself has never been a major industrial centre; historically, its importance has been much more in trade and commerce. Nevertheless, certain industries did develop in Marseille. The oldest, founded in the 15th century, was the manufacture of soap from olive oil produced in the surrounding district. Other activities included food processing (linked to both imported agricultural products and those originating from the surrounding region), shipbuilding and ship repair, metallurgy, clothing, chemicals, and precision engineering. Many of these industries have either disappeared (as in the case of shipbuilding) or been reduced in importance through loss of markets or transfer to the city's periphery. Heavy industry (oil refining and petrochemicals) grew up around the Berre Lagoon in the 1950s following the building of an outport at Lavéra capable of receiving large oil tankers. This trend was accelerated from the late 1960s with the opening of the Fos port-industrial complex and with the addition of more petrochemical plants as well as steelworks. The majority of these installations use raw materials that enter through the port of Fos, and some of their finished products also leave by sea. The industrial zone is also directly linked to the national rail and highway networks, to the South European Pipeline, and to the Rhône inland waterway.

Port development

Lighter industrial development, warehousing, and transport-related activities have also greatly expanded north to the outlying districts of Marignane (site of Marseille's international airport) and Vitrolles. A similar trend is evident to the east along the Huveaune valley in the direction of Aubagne. Within Marseille itself a number of new industrial and related service activities have become established in fields such as electronics, data processing, telecommunications, and biomedicine. New sites have also been developed, including the Château-Gombert science park in the city's northeastern suburbs. The city's maritime location and traditions have also led to the growth of industries and services in offshore exploration and engineering.

The port complex of Marseille–Fos is the largest in France and among the largest in Europe. It is administered by the Port Autonome de Marseille ("Autonomous Port of Marseille"), a financially autonomous state enterprise that is responsible for the construction, administration, and maintenance of the industrial zones at Fos and Lavéra and the port facilities at Marseille, Lavéra, Caronte, Fos, and Port-Saint-Louis-du-Rhône. In addition to administering Marseille–Fos, the Port Autonome de Marseille also provides advice, information, and planning services for port authorities around the world. It is financed by rents, taxes, and fees for services, with state aid for investment in construction of harbours and quays.

In recent years the commercial traffic of the port complex has exceeded 90 million tons annually. The majority of this total is imports, mostly crude oil. Other imports include refined oil products, liquified natural gas, chemical products, and raw materials for the steel and aluminum industries. Exports consist mostly of refined oil products, chemicals, and steel. Containerized traffic of general merchandise is rising.

The different port zones have become increasingly specialized. Marseille itself handles roll-on/roll-off traffic (of both passengers and freight, principally to Corsica and North Africa), visits of cruise liners, and some bulk food products. Lavéra specializes in petroleum and chemical products, and Fos handles oil, other dry and liquid bulk cargoes, and containers. At Marseille there are also large ship repair yards, though their importance has greatly diminished.

Commerce and finance. Because of its geographic position and its commercial importance, Marseille has long been able to attract foreign capital. In the mid-19th century two major banks were established: the Société de Crédit Foncier de Marseille in 1852 and the Société Marseillaise de Crédit Industriel et Commercial et de Dépôts in 1865. Local money was directed both into industrial projects in the region and into foreign ventures such as the Suez Canal Company. But the disintegration of the French empire during the 20th century helped to accelerate the decline of Marseille as a financial centre. In this respect the relative lack of regional headquarters of large multinational firms represents another weakness in the city's economy.

Nonetheless, as capital of the Provence-Alpes-Côte d'Azur *région*, Marseille has considerable financial influence in the public sector. The Centre Méditerranéen de Commerce International (Mediterranean Centre for International Trade) was opened in 1983 to reassert the position of Marseille as a commercial and financial centre. It is anticipated that the Euroméditerranée complex will further enhance the city's role as a business capital.

Transportation. Marseille has good external connections. Two highways provide access to the north, and another highway reaches the city from the east. The high-

Innovations in transportation facilities

speed train (TGV; Train à Grande Vitesse), running on purpose-built track, makes it possible to reach Lyon in one hour and Paris in three. To the north of the city, the Marseille-Provence Airport (France's third-ranking airport for passenger traffic, after Paris and Nice) provides links to several destinations in France, Europe, and North Africa.

Within the city, movement is more problematic. Road congestion is severe, despite a tunnel under the centre linking the northern and eastern highways. Public transportation has been improved with the introduction of two underground metro lines and a surface tramway serving part of the eastern suburbs.

ADMINISTRATION AND SOCIAL CONDITIONS

Government. The city government consists of a popularly elected municipal council. The council keeps very much alive the historical tradition of local independence in spite of the intimate involvement of many national ministries in the financing and planning of projects throughout the area.

The city is divided into 16 *arrondissements,* but for the purposes of local government these are grouped into eight *secteurs,* which elect mayors. In addition to the eight city halls, one for each *secteur,* there are two "mini city halls" in each *arrondissement.* The city mayor is assisted by a local government of 27 *adjoints,* each with responsibility for a particular facet of government, such as town planning, culture, finance, employment, or transport, and by delegate councillors who assist the *adjoints* or undertake more detailed responsibilities.

Services. The city's *adjoints* oversee the main urban services administered by the local authorities: lighting, refuse disposal, relations with the police and fire services, and so on. An unemployment rate above the national average and a large population of immigrant workers has exacerbated the problem of providing public services. In summer the region is particularly threatened by forest fires, and Marseille is the centre from which fire fighting is coordinated. A fleet of specially equipped airplanes is stationed at the airport.

Health. There are two teaching hospital complexes in Marseille, the North Hospital and the Timone Hospital. The centre for the study of tropical medicine at the Michel Lévy Hospital is well known. A computer centre in the suburb of Luminy links the region's hospitals.

Education. Three universities have sites in the city. The University of Aix-Marseille I offers courses in the sciences in Marseille (with courses in the arts and social sciences offered in Aix-en-Provence). The University of Aix-Marseille II has its faculty of medicine in Marseille, and the University of Aix-Marseille III has units in the sciences and engineering in the city. Both Aix and Marseille also have technical universities. In addition, there is a series of graduate schools specializing in fields such as physics, management, and engineering.

CULTURAL LIFE

Marseille has several museums, including a very popular Children's Museum. The Museum of Old Marseille was installed in 1960 next to the City Hall in Diamond House (La Maison Diamantée), so called because of its 16th-century facade of projecting diamond-shaped stone lozenges. The Cantini Museum, close to the rue Paradis, east of the Old Port, has a fine collection of Oriental art, of local pottery, and of modern paintings and sculptures.

Marseille has a number of historic sites and monuments, including its most famous landmark, the basilica of Notre-Dame-de-la-Garde, perched high above the city. It has an opera house, is an important centre for the theatre and music, and has a national dance school with a national ballet company. All of these activities are administered by the Municipal Office of Culture. The city has tried to reflect the diverse cultures of Marseille by encouraging exchanges with artists and companies from Algeria and other North African countries. During the 1930s, Marcel Pagnol founded a film studio in Marseille that made the city, for a time, France's only centre of the industry outside the Paris region.

As building has increased within Marseille, more attention has been paid to the conservation and development of the municipality's parks and playgrounds. There are a large number of municipal sports centres and swimming pools, an outdoor theatre, and public beaches (centred around the Prado district and its aquarium). The parks of the Château du Pharo, Château Borély, and Palais Longchamp are extensive.

History

THE EARLY PERIOD

The oldest of the large French cities, Marseille was founded as Massalia (Massilia) by Greek mariners from Phocaea in Asia Minor about 600 BC. Archaeological finds exhibited in the Museum of Antiquities in the 18th-century Château Borély suggest that Phoenicians had settled there even earlier.

Antiquity and the Middle Ages. The Massalians spread trading posts inland as well as along the coasts, westward to Spain, and eastward to Monaco, founding the present cities of Arles, Nice, Antibes, Agde, and La Ciotat. Their coins have been found across France and through the Alps as far as the Tirol. In the 4th century BC a Massalian, Pytheas, visited the coasts of Gaul, Britain, and Germany, and a Euthymenes is said to have navigated the west coast of Africa as far south as Senegal.

When their great trade rivals, the Carthaginians, fought the Romans in the Punic Wars, Marseille supported the Romans and received help in subduing the native tribes of Liguria. When Pompey and Julius Caesar clashed, Marseille took Pompey's side and subsequently fell to Caesar's lieutenant Trebonius in 49 BC. Although stripped of dependencies, it was permitted to retain its status as a free city in recognition of past services. For some time the city remained the last centre of Greek learning in the West, but, eventually, it declined almost to extinction. After centuries of invasion and epidemic, it became little more than a huddle of nearly abandoned ruins.

Decline and resuscitation

In the 10th century, under the protection of successive viscounts of Provence, the area was repopulated, and it found new prosperity as a shipping and staging point for the Crusades. Gradually, the town bought up the rights of the viscounts, and, at the beginning of the 13th century, it formed a republic around the Old Port, though the upper part of the city and its southern suburb remained under ecclesiastical jurisdiction. The counts of Provence allowed the city great independence, and only in 1245 and 1256 did Charles of Anjou force acknowledgement of his sovereignty. After Marseille was sacked by Alfonso V of Aragon in 1423, King René of Provence, whose winter residence was there, restored prosperity to the city.

Uneasy union with France. When Provence, including Marseille, became part of the kingdom of France in 1481, the city preserved a separate administration directed by royal officials. During the 16th-century wars of religion, Marseille was fanatically Roman Catholic and long refused to recognize Henry IV as king because, until his conversion to Catholicism and accession to the French throne, he had been leader of the Protestants. During the Fronde, a movement in 1648–53 that opposed royal absolutism, the city sought to conserve its ancient liberties and rose against Louis XIV, who in 1660 came in person, breached the walls, and subdued the revolt. To discourage further manifestations of independence, the king planted Fort Saint-Nicolas at the southern extremity of the Old Port. In the same year, the city pushed inland to the west beyond its walls. A few buildings constructed in this expansion still survive in the area around the Cours Belsunce—a major thoroughfare—and the Préfecture.

Marseille joined enthusiastically in the French Revolution. Some 500 volunteers marching to Paris in 1792 sang "The War Song of the Rhine Army," which had been composed in Strasbourg in the late 18th century. The song, which thrilled the crowds along the route of march, was renamed "La Marseillaise" and became the national anthem of France. As the early federalist concepts were washed away in the blood of the Reign of Terror, however, the city revolted against the ruling Convention. Quickly mastered by force of arms, it was officially designated as "the city without a name." When its commerce was al-

Marseille and the Revolution

most destroyed by the maritime blockade of the Continent directed against Napoleon, Marseille became bitterly anti-Bonapartist and hailed the Bourbon restoration. Under Napoleon III, however, it remained stubbornly republican.

Era of expansion. During the second half of the 19th century, Marseille was expanded as the "port of empire," gaining impetus from the elimination of the Barbary pirates (1815–35), the conquest of Algeria (1830), and the inauguration of the Suez Canal (1869). The great avenues and many of the monuments of the city were constructed in this period. A serious water problem was solved by a project (1837–48) that brought water from the Durance River. The distribution reservoir above the city was disguised as the Longchamp Palace, containing the Museum of Natural History and the Museum of Fine Arts. The Château du Pharo, one of the city's principal landmarks, was built as a villa for Napoleon III and Eugénie at the edge of the bay beyond the Old Port, but it was never occupied by the imperial couple. The Bourse, an imposing colonnaded structure on La Canebière, was built in 1852–60 to house the Chamber of Commerce.

THE MODERN CITY

The city, occupied by the German army from November 1942 until August 1944, continued to be an active centre of the French Resistance movement, which partly explains the German decision to dynamite the Panier district and the Old Port in 1943. Further destruction was caused by German mines in August 1944.

The postwar history of Marseille is initially the story of the rebuilding of areas damaged in the war and the development of industrial and port complexes around Fos. It is also the story of a redistribution of population and economic activity. Central districts have lost population and have experienced industrial decline, particularly in areas adjacent to the 19th-century port, while peripheral zones have expanded massively, acquiring large housing estates and new industrial and commercial parks. Marseille remains an important economic centre, though its influence in southeastern France is rivaled by the city of Lyon.

BIBLIOGRAPHY

General works: Chapters on Marseille, including maps, photographs, and site descriptions, can be found in numerous tour guides, such as *The Green Guide: Provence* (2000), by Michelin Travel Publications; and *Provence and the Côte d'Azur,* updated ed. (2001), in the Fodor's Guides series. ARCHIBALD LYALL, *The Companion Guide to the South of France,* 3rd ed. rev. and expanded by A.N. BRANGHAM (1972, reprinted 1996); and IAN B. THOMPSON, *The Lower Rhone and Marseille* (1975), include discussions of the topography, principal monuments, and cultural institutions of Marseille. M.F.K. FISHER, *A Considerable Town* (1978), presents vignettes on the city and its people by a noted American food and travel writer. ANDRÉ REMACLE, *Marseille à coeur ouvert* (1981), gives the personal view of a Marseille journalist and deals with the character and history of the city.

PAUL CARRÈRE and RAYMOND DUGRAND, *La Région Méditerranéenne,* 2nd rev. ed. (1967), deals with the city's industrial region. GILBERT ROCHU, *Marseille, les années Defferre* (1983), is a critical analysis of the administration of the city in the period since World War II. More recent works on the development of Marseille include A. MÉDAM, *Blues Marseille* (1995); DOMINIQUE BECQUART, *Marseille, 25 ans de planification urbaine* (1994); JEAN-LUCIEN BONILLO *et al., Marseille, ville & port* (1992); JEAN VIARD, *Marseille, une ville impossible* (1995); and MARCEL RONCAYOLO, *Marseille: les territoires du temps* (1996).

History: Two comprehensive histories in French are GASTON RAMBERT (ed.), *Histoire du commerce de Marseille,* 6 vol. (1949–59); and RAOUL BUSQUET, *Histoire de Marseille,* new ed., rev. and updated by CONSTANT VAUTRAVERS (1998). LUCIEN GAILLARD, *Marseille sous l'occupation* (1982), covers the occupation years of World War II and is illustrated with contemporary photographs and reproductions of documents.

(B.E./R.C.Bu./J.N.T.)

Marx and Marxism

Karl Marx, revolutionary, sociologist, historian, and economist, was the author (with Friedrich Engels) of *Manifest der Kommunistischen Partei* (1848), commonly known as *The Communist Manifesto*, the most celebrated pamphlet in the history of the socialist movement, as well as of its most important book, *Das Kapital*. These writings and others by Marx and Engels form the basis of the body of thought and belief known as Marxism.

This article deals with Marx's life, his thinking, his accomplishments, and the development of Marxist theory. See the article SOCIO-ECONOMIC DOCTRINES AND REFORM MOVEMENTS, MODERN, for a full treatment of socialism and communism. For coverage of related topics in the *Macropædia* and *Micropædia*, see the *Propædia*, section 541, and the *Index*.

The article is divided into the following sections:

Life and works of Marx

EARLY YEARS

Karl Heinrich Marx was born on May 5, 1818, in the city of Trier in the Rhine province of Prussia, now in Germany. He was the oldest surviving boy of nine children. His father, Heinrich, a successful lawyer, was a man of the Enlightenment, devoted to Kant and Voltaire, who took part in agitations for a constitution in Prussia. His mother, born Henrietta Pressburg, was from Holland. Both parents were Jewish and were descended from a long line of rabbis, but, a year or so before Karl was born, his father—probably because his professional career required it—was baptized in the Evangelical Established Church. Karl was baptized when he was six years old. Although as a youth Karl was influenced less by religion than by the critical, sometimes radical social policies of the Enlightenment, his Jewish background exposed him to prejudice and discrimination that may have led him to question the role of religion in society and contributed to his desire for social change.

Early education

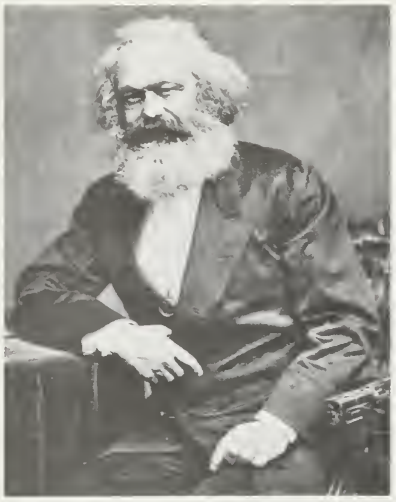
Marx was educated from 1830 to 1835 at the high school in Trier. Suspected of harbouring liberal teachers and pupils, the school was under police surveillance. Marx's writings during this period exhibited a spirit of Christian devotion and a longing for self-sacrifice on behalf of humanity. In October 1835 he matriculated at the University of Bonn. The courses he attended were exclusively in the humanities, in such subjects as Greek and Roman mythology and the history of art. He participated in customary student activities, fought a duel, and spent a day in jail for being drunk and disorderly. He presided at the Tavern Club, which was at odds with the more aristocratic student associations, and joined a poets' club that included some political activists. A politically rebellious student culture was, indeed, part of life at Bonn. Many students had been arrested; some were still being expelled in Marx's time, particularly as a result of an effort by students to disrupt a session of the Federal Diet at Frankfurt. Marx, however, left Bonn after a year and in October 1836 enrolled at the University of Berlin to study law and philosophy.

Marx's crucial experience at Berlin was his introduction to Hegel's philosophy, regnant there, and his adherence to the Young Hegelians. At first he felt a repugnance toward Hegel's doctrines; when Marx fell sick it was partially, as he wrote his father, "from intense vexation at having to make an idol of a view I detested." The Hegelian pressure in the revolutionary student culture was powerful, however, and Marx joined a society called the Doctor Club, whose members were intensely involved in the new literary and philosophical movement. Their chief figure was Bruno Bauer, a young lecturer in theology, who was developing the idea that the Christian Gospels were a record not of history but of human fantasies arising from emotional needs and that Jesus had not been a historical person. Marx enrolled in a course of lectures given by Bauer on the prophet Isaiah. Bauer taught that a new social catastrophe "more tremendous" than that of the advent of Christianity was in the making. The Young Hegelians began moving rapidly toward atheism and also talked vaguely of political action.

The Prussian government, fearful of the subversion latent in the Young Hegelians, soon undertook to drive them from the universities. Bauer was dismissed from his post in 1839. Marx's "most intimate friend" of this period, Adolph Rutenberg, an older journalist who had served a prison sentence for his political radicalism, pressed for a deeper social involvement. By 1841 the Young Hegelians had become left republicans. Marx's studies, meanwhile, were lagging. Urged by his friends, he submitted a doctoral dissertation to the university at Jena, which was known to be lax in its academic requirements, and received his degree in April 1841. His thesis analyzed in a Hegelian fashion the difference between the natural philosophies of Democritus and Epicurus. More distinctively, it sounded a note of Promethean defiance:

> Philosophy makes no secret of it. Prometheus' admission: "In sooth all gods I hate," is its own admission, its own motto against all gods, . . . Prometheus is the noblest saint and martyr in the calendar of philosophy.

In 1841 Marx, together with other Young Hegelians, was much influenced by the publication of *Das Wesen des Christentums* (1841; *The Essence of Christianity*) by Ludwig Feuerbach. Its author, to Marx's mind, successfully criticized Hegel, an idealist who believed that matter or existence was inferior to and dependent upon mind or spirit, from the opposite, or materialist, standpoint, showing how the "Absolute Spirit" was a projection of "the real man standing on the foundation of nature." Henceforth Marx's philosophical efforts were toward a combination of



Marx.

Hegel's dialectic—the idea that all things are in a continual process of change resulting from the conflicts between their contradictory aspects—with Feuerbach's materialism, which placed material conditions above ideas.

In January 1842 Marx began contributing to a newspaper newly founded in Cologne, the *Rheinische Zeitung*. It was the liberal democratic organ of a group of young merchants, bankers, and industrialists; Cologne was the centre of the most industrially advanced section of Prussia. To this stage of Marx's life belongs an essay on the freedom of the press. Since he then took for granted the existence of absolute moral standards and universal principles of ethics, he condemned censorship as a moral evil that entailed spying into people's minds and hearts and assigned to weak and malevolent mortals powers that presupposed an omniscient mind. He believed that censorship could have only evil consequences.

Newspaper work

On Oct. 15, 1842, Marx became editor of the *Rheinische Zeitung*. As such, he was obliged to write editorials on a variety of social and economic issues, ranging from the housing of the Berlin poor and the theft by peasants of wood from the forests to the new phenomenon of communism. He found Hegelian idealism of little use in these matters. At the same time he was becoming estranged from his Hegelian friends for whom shocking the bourgeois was a sufficient mode of social activity. Marx, friendly at this time to the "liberal-minded practical men" who were "struggling step-by-step for freedom within constitutional limits," succeeded in trebling his newspaper's circulation and making it a leading journal in Prussia. Nevertheless, Prussian authorities suspended it for being too outspoken, and Marx agreed to coedit with the liberal Hegelian Arnold Ruge a new review, the *Deutsch-französische Jahrbücher* ("German-French Yearbooks"), which was to be published in Paris.

First, however, in June 1843 Marx, after an engagement of seven years, married Jenny von Westphalen. Jenny was an attractive, intelligent, and much-admired woman, four years older than Karl; she came of a family of military and administrative distinction. Her half-brother later became a highly reactionary Prussian minister of the interior. Her father, a follower of the French socialist Saint-Simon, was fond of Karl, though others in her family opposed the marriage. Marx's father also feared that Jenny was destined to become a sacrifice to the demon that possessed his son.

Four months after their marriage, the young couple moved to Paris, which was then the centre of socialist thought and of the more extreme sects that went under the name of communism. There, Marx first became a revolutionary and a communist and began to associate with communist societies of French and German workingmen. Their ideas were, in his view, "utterly crude and unintelligent," but their character moved him: "The brotherhood of man is no mere phrase with them, but a fact of life, and the nobility of man shines upon us from their work-hardened bodies," he wrote in his so-called "Ökonomisch-philosophische Manuskripte aus dem Jahre 1844" (written in 1844; *Economic and Philosophic Manuscripts of 1844* [1959]). (These manuscripts were not published for some 100 years, but they are influential because they show the humanist background to Marx's later historical and economic theories.)

The "German-French Yearbooks" proved short-lived, but through their publication Marx befriended Friedrich Engels, a contributor who was to become his lifelong collaborator, and in their pages appeared Marx's article "Zur Kritik der Hegelschen Rechtsphilosophie" ("Toward the Critique of the Hegelian Philosophy of Right") with its oft-quoted assertion that religion is the "opium of the people." It was there, too, that he first raised the call for an "uprising of the proletariat" to realize the conceptions of philosophy. Once more, however, the Prussian government intervened against Marx. He was expelled from France and left for Brussels—followed by Engels—in February 1845. That year in Belgium he renounced his Prussian nationality.

BRUSSELS PERIOD

Collaboration with Engels

The next two years in Brussels saw the deepening of Marx's collaboration with Engels. Engels had seen at firsthand in Manchester, Eng., where a branch factory of his father's textile firm was located, all the depressing aspects of the Industrial Revolution. He had also been a Young Hegelian and had been converted to communism by Moses Hess, who was called the "communist rabbi." In England he associated with the followers of Robert Owen. Now he and Marx, finding that they shared the same views, combined their intellectual resources and published *Die heilige Familie* (1845; *The Holy Family*), a prolix criticism of the Hegelian idealism of the theologian Bruno Bauer. Their next work, *Die deutsche Ideologie* (written 1845–46, published 1932; *The German Ideology*), contained the fullest exposition of their important materialistic conception of history, which set out to show how, historically, societies had been structured to promote the interests of the economically dominant class. But it found no publisher and remained unknown during its authors' lifetimes.

During his Brussels years, Marx developed his views and, through confrontations with the chief leaders of the working-class movement, established his intellectual standing. In 1846 he publicly excoriated the German leader Wilhelm Weitling for his moralistic appeals. Marx insisted that the stage of bourgeois society could not be skipped over; the proletariat could not just leap into communism; the workers' movement required a scientific basis, not moralistic phrases. He also polemicized against the French socialist thinker Pierre-Joseph Proudhon in *Misère de la philosophie* (1847; *The Poverty of Philosophy*), a mordant attack on Proudhon's book subtitled *Philosophie de la misère* (1846; *The Philosophy of Poverty*). Proudhon wanted to unite the best features of such contraries as competition and monopoly; he hoped to save the good features in economic institutions while eliminating the bad. Marx, however, declared that no equilibrium was possible between the antagonisms in any given economic system. Social structures were transient historic forms determined by the productive forces: "The handmill gives you society with the feudal lord; the steammill, society with the industrial capitalist." Proudhon's mode of reasoning, Marx wrote, was typical of the petty bourgeois, who failed to see the underlying laws of history.

The Communist Manifesto

An unusual sequence of events led Marx and Engels to write their pamphlet *The Communist Manifesto*. In June 1847 a secret society, the League of the Just, composed mainly of emigrant German handicraftsmen, met in London and decided to formulate a political program. They sent a representative to Marx to ask him to join the league; Marx overcame his doubts and, with Engels, joined the organization, which thereupon changed its name to the Communist League and enacted a democratic constitution. Entrusted with the task of composing their program, Marx and Engels worked from the middle of December 1847 to the end of January 1848. The London Communists were already impatiently threatening Marx with

disciplinary action when he sent them the manuscript; they promptly adopted it as their manifesto. It enunciated the proposition that all history had hitherto been a history of class struggles, summarized in pithy form the materialist conception of history worked out in *The German Ideology,* and asserted that the forthcoming victory of the proletariat would put an end to class society forever. It mercilessly criticized all forms of socialism founded on philosophical "cobwebs" such as "alienation." It rejected the avenue of "social Utopias," small experiments in community, as deadening the class struggle and therefore as being "reactionary sects." It set forth 10 immediate measures as first steps toward communism, ranging from a progressive income tax and the abolition of inheritances to free education for all children. It closed with the words, "The proletarians have nothing to lose but their chains. They have a world to win. Workingmen of all countries, unite!"

Participation in the events of 1848

Revolution suddenly erupted in Europe in the first months of 1848, in France, Italy, and Austria. Marx had been invited to Paris by a member of the provisional government just in time to avoid expulsion by the Belgian government. As the revolution gained in Austria and Germany, Marx returned to the Rhineland. In Cologne he advocated a policy of coalition between the working class and the democratic bourgeoisie, opposing for this reason the nomination of independent workers' candidates for the Frankfurt Assembly and arguing strenuously against the program for proletarian revolution advocated by the leaders of the Workers' Union. He concurred in Engels' judgment that *The Communist Manifesto* should be shelved and the Communist League disbanded. Marx pressed his policy through the pages of the *Neue Rheinische Zeitung,* newly founded in June 1849, urging a constitutional democracy and war with Russia. When the more revolutionary leader of the Workers' Union, Andreas Gottschalk, was arrested, Marx supplanted him and organized the first Rhineland Democratic Congress in August 1848. When the king of Prussia dissolved the Prussian Assembly in Berlin, Marx called for arms and men to help the resistance. Bourgeois liberals withdrew their support from Marx's newspaper, and he himself was indicted on several charges, including advocacy of the nonpayment of taxes. In his trial he defended himself with the argument that the crown was engaged in making an unlawful counterrevolution. The jury acquitted him unanimously and with thanks. Nevertheless, as the last hopeless fighting flared in Dresden and Baden, Marx was ordered banished as an alien on May 16, 1849. The final issue of his newspaper, printed in red, caused a great sensation.

EARLY YEARS IN LONDON

Expelled once more from Paris, Marx went to London in August 1849. It was to be his home for the rest of his life. Chagrined by the failure of his own tactics of collaboration with the liberal bourgeoisie, he rejoined the Communist League in London and for about a year advocated a bolder revolutionary policy. An "Address of the Central Committee to the Communist League," written with Engels in March 1850, urged that in future revolutionary situations they struggle to make the revolution "permanent" by avoiding subservience to the bourgeois party and by setting up "their own revolutionary workers' governments" alongside any new bourgeois one. Marx hoped that the economic crisis would shortly lead to a revival of the revolutionary movement; when this hope faded, he came into conflict once more with those whom he called "the alchemists of the revolution," such as August von Willich, a communist who proposed to hasten the advent of revolution by undertaking direct revolutionary ventures. Such persons, Marx wrote in September 1850, substitute "idealism for materialism" and regard

pure will as the motive power of revolution instead of actual conditions. While we say to the workers: "You have got to go through fifteen, twenty, fifty years of civil wars and national wars not merely in order to change your conditions but in order to change yourselves and become qualified for political power," you on the contrary tell them, "We must achieve power immediately."

The militant faction in turn ridiculed Marx for being a revolutionary who limited his activity to lectures on political economy to the Communist Workers' Educational Union. The upshot was that Marx gradually stopped attending meetings of the London Communists. In 1852 he devoted himself intensely to working for the defense of 11 communists arrested and tried in Cologne on charges of revolutionary conspiracy and wrote a pamphlet on their behalf. The same year he also published, in a German-American periodical, his essay "Der Achtzehnte Brumaire des Louis Napoleon" (*The Eighteenth Brumaire of Louis Bonaparte*), with its acute analysis of the formation of a bureaucratic absolutist state with the support of the peasant class. In other respects the next 12 years were, in Marx's words, years of "isolation" both for him and for Engels in his Manchester factory.

Poverty in London

From 1850 to 1864 Marx lived in material misery and spiritual pain. His funds were gone, and except on one occasion he could not bring himself to seek paid employment. In March 1850 he and his wife and four small children were evicted and their belongings seized. Several of his children died—including a son Guido, "a sacrifice to bourgeois misery," and a daughter Franziska, for whom his wife rushed about frantically trying to borrow money for a coffin. For six years the family lived in two small rooms in Soho, often subsisting on bread and potatoes. The children learned to lie to the creditors: "Mr. Marx ain't upstairs." Once he had to escape them by fleeing to Manchester. His wife suffered breakdowns.

During all these years Engels loyally contributed to Marx's financial support. The sums were not large at first, for Engels was only a clerk in the firm of Ermen and Engels at Manchester. Later, however, in 1864, when he became a partner, his subventions were generous. Marx was proud of Engels' friendship and would tolerate no criticism of him. Bequests from the relatives of Marx's wife and from Marx's friend Wilhelm Wolff also helped to alleviate their economic distress.

Marx had one relatively steady source of earned income in the United States. On the invitation of Charles A. Dana, managing editor of *The New York Tribune,* he became in 1851 its European correspondent. The newspaper, edited by Horace Greeley, had sympathies for Fourierism, a Utopian socialist system developed by the French theorist Charles Fourier. From 1851 to 1862 Marx contributed close to 500 articles and editorials (Engels providing about a fourth of them). He ranged over the whole political universe, analyzing social movements and agitations from India and China to Britain and Spain.

In 1859 Marx published his first book on economic theory, *Zur Kritik der politischen Ökonomie* (*A Contribution to the Critique of Political Economy*). In its preface he again summarized his materialistic conception of history, his theory that the course of history is dependent on economic developments. At this time, however, Marx regarded his studies in economic and social history at the British Museum as his main task. He was busy producing the drafts of his magnum opus, which was to be published later as *Das Kápital.* Some of these drafts, including the *Outlines* and the *Theories of Surplus Value,* are important in their own right and were published after Marx's death.

ROLE IN THE FIRST INTERNATIONAL

Marx's political isolation ended in 1864 with the founding of the International Working Men's Association. Although he was neither its founder nor its head, he soon became its leading spirit. Its first public meeting, called by English trade union leaders and French workers' representatives, took place at St. Martin's Hall in London on Sept. 28, 1864. Marx, who had been invited through a French intermediary to attend as a representative of the German workers, sat silently on the platform. A committee was set up to produce a program and a constitution for the new organization. After various drafts had been submitted that were felt to be unsatisfactory, Marx, serving on a subcommittee, drew upon his immense journalistic experience. His "Address and the Provisional Rules of the International Working Men's Association," unlike his other writings, stressed the positive achievements of the cooperative

movement and of parliamentary legislation; the gradual conquest of political power would enable the British proletariat to extend these achievements on a national scale.

As a member of the organization's General Council, and corresponding secretary for Germany, Marx was henceforth assiduous in attendance at its meetings, which were sometimes held several times a week. For several years he showed a rare diplomatic tact in composing differences among various parties, factions, and tendencies. The International grew in prestige and membership, its numbers reaching perhaps 800,000 in 1869. It was successful in several interventions on behalf of European trade unions engaged in struggles with employers.

The Paris Commune

In 1870, however, Marx was still unknown as a European political personality; it was the Paris Commune that made him into an international figure, "the best calumniated and most menaced man of London," as he wrote. When the Franco-German War broke out in 1870, Marx and Engels disagreed with followers in Germany who refused to vote in the Reichstag in favour of the war. The General Council declared that "on the German side the war was a war of defence." After the defeat of the French armies, however, they felt that the German terms amounted to aggrandizement at the expense of the French people. When an insurrection broke out in Paris and the Paris Commune was proclaimed, Marx gave it his unswerving support. On May 30, 1871, after the Commune had been crushed, he hailed it in a famous address entitled *Civil War in France:*

> History has no comparable example of such greatness.... Its martyrs are enshrined forever in the great heart of the working class.

In Engels' judgment, the Paris Commune was history's first example of the "dictatorship of the proletariat." Marx's name, as the leader of The First International and author of the notorious *Civil War,* became synonymous throughout Europe with the revolutionary spirit symbolized by the Paris Commune.

The advent of the Commune, however, exacerbated the antagonisms within the International Working Men's Association and thus brought about its downfall. English trade unionists such as George Odger, former president of the General Council, opposed Marx's support of the Paris Commune. The Reform Bill of 1867, which had enfranchised the British working class, had opened vast opportunities for political action by the trade unions. English labour leaders found they could make many practical advances by cooperating with the Liberal Party and, regarding Marx's rhetoric as an encumbrance, resented his charge that they had "sold themselves" to the Liberals.

The struggle with Bakunin

A left opposition also developed under the leadership of the famed Russian revolutionary Mikhail Alexandrovich Bakunin. A veteran of tsarist prisons and Siberian exile, Bakunin could move men by his oratory, which one listener compared to "a raging storm with lightning, flashes and thunderclaps, and a roaring as of lions." Bakunin admired Marx's intellect but could hardly forget that Marx had published a report in 1848 charging him with being a Russian agent. He felt that Marx was a German authoritarian and an arrogant Jew who wanted to transform the General Council into a personal dictatorship over the workers. He strongly opposed several of Marx's theories, especially Marx's support of the centralized structure of the International, Marx's view that the proletariat class should act as a political party against prevailing parties but within the existing parliamentary system, and Marx's belief that the proletariat, after it had overthrown the bourgeois state, should establish its own regime. To Bakunin, the mission of the revolutionary was destruction; he looked to the Russian peasantry, with its propensities for violence and its uncurbed revolutionary instincts, rather than to the effete, civilized workers of the industrial countries. The students, he hoped, would be the officers of the revolution. He acquired followers, mostly young men, in Italy, Switzerland, and France, and he organized a secret society, the International Alliance of Social Democracy, which in 1869 challenged the hegemony of the General Council at the congress in Basel, Switz. Marx, however, had already succeeded in preventing its admission as an organized body into the International.

To the Bakuninists, the Paris Commune was a model of revolutionary direct action and a refutation of what they considered to be Marx's "authoritarian communism." Bakunin began organizing sections of the International for an attack on the alleged dictatorship of Marx and the General Council. Marx in reply publicized Bakunin's embroilment with an unscrupulous Russian student leader, Sergey Gennadiyevich Nechayev, who had practiced blackmail and murder.

Without a supporting right wing and with the anarchist left against him, Marx feared losing control of the International to Bakunin. He also wanted to return to his studies and to finish *Das Kapital.* At the congress of the International at The Hague in 1872, the only one he ever attended, Marx managed to defeat the Bakuninists. Then, to the consternation of the delegates, Engels moved that the seat of the General Council be transferred from London to New York City. The Bakuninists were expelled, but the International languished and was finally disbanded in Philadelphia in 1876.

Dissolution of the International

LAST YEARS

During the next and last decade of his life, Marx's creative energies declined. He was beset by what he called "chronic mental depression," and his life turned inward toward his family. He was unable to complete any substantial work, though he still read widely and undertook to learn Russian. He became crotchety in his political opinions. When his own followers and those of the German revolutionary Ferdinand Lassalle, a rival who believed that socialist goals should be achieved through cooperation with the state, coalesced in 1875 to found the German Social Democratic Party, Marx wrote a caustic criticism of their program (the so-called Gotha Program), claiming that it made too many compromises with the status quo. The German leaders put his objections aside and tried to mollify him personally. Increasingly, he looked to a European war for the overthrow of Russian tsarism, the mainstay of reaction, hoping that this would revive the political energies of the working classes. He was moved by what he considered to be the selfless courage of the Russian terrorists who assassinated the tsar, Alexander II, in 1881; he felt this to be "a historically inevitable means of action."

Despite Marx's withdrawal from active politics, he still retained what Engels called his "peculiar influence" on the leaders of working-class and socialist movements. In 1879, when the French Socialist Workers' Federation was founded, its leader Jules Guesde went to London to consult with Marx, who dictated the preamble of its program and shaped much of its content. In 1881 Henry Mayers Hyndman in his *England for All* drew heavily on his conversations with Marx but angered him by being afraid to acknowledge him by name.

During his last years Marx spent much time at health resorts and even traveled to Algiers. He was broken by the death of his wife on Dec. 2, 1881, and of his eldest daughter, Jenny Longuet, on Jan. 11, 1883. He died in London, evidently of a lung abscess, on March 14, 1883.

Death

CHARACTER AND SIGNIFICANCE

At Marx's funeral in Highgate Cemetery, Engels declared that Marx had made two great discoveries, the law of development of human history and the law of motion of bourgeois society. But "Marx was before all else a revolutionist." He was "the best-hated and most-calumniated man of his time," yet he also died "beloved, revered and mourned by millions of revolutionary fellow-workers."

The contradictory emotions Marx engendered are reflected in the sometimes conflicting aspects of his character. Marx was a combination of the Promethean rebel and the rigorous intellectual. He gave most persons an impression of intellectual arrogance. A Russian writer, Pavel Annenkov, who observed Marx in debate in 1846 recalled that "he spoke only in the imperative, brooking no contradiction," and seemed to be "the personification of a democratic dictator such as might appear before one in moments of fantasy." But Marx obviously felt uneasy before mass audiences and avoided the atmosphere of factional controversies at congresses. He went to no

demonstrations, his wife remarked, and rarely spoke at public meetings. He kept away from the congresses of the International where the rival socialist groups debated important resolutions. He was a "small groups" man, most at home in the atmosphere of the General Council or on the staff of a newspaper, where his character could impress itself forcefully on a small body of coworkers. At the same time he avoided meeting distinguished scholars with whom he might have discussed questions of economics and sociology on a footing of intellectual equality. Despite his broad intellectual sweep, he was prey to obsessive ideas such as that the British foreign minister, Lord Palmerston, was an agent of the Russian government. He was determined not to let bourgeois society make "a money-making machine" out of him, yet he submitted to living on the largess of Engels and the bequests of relatives. He remained the eternal student in his personal habits and way of life, even to the point of joining two friends in a students' prank during which they systematically broke four or five streetlamps in a London street and then fled from the police. He was a great reader of novels, especially those of Sir Walter Scott and Balzac; and the family made a cult of Shakespeare. He was an affectionate father, saying that he admired Jesus for his love of children, but sacrificed the lives and health of his own. Of his seven children, three daughters grew to maturity. His favourite daughter, Eleanor, worried him with her nervous, brooding, emotional character and her desire to be an actress. Another shadow was cast on Marx's domestic life by the birth to their loyal servant, Helene Demuth, of an illegitimate son, Frederick; Engels as he was dying disclosed to Eleanor that Marx had been the father. Above all, Marx was a fighter, willing to sacrifice anything in the battle for his conception of a better society. He regarded struggle as the law of life and existence.

Das Kapital

The influence of Marx's ideas has been enormous. Marx's masterpiece, *Das Kapital*, the "Bible of the working class," as it was officially described in a resolution of the International Working Men's Association, was published in 1867 in Berlin and received a second edition in 1873. Only the first volume was completed and published in Marx's lifetime. The second and third volumes, unfinished by Marx, were edited by Engels and published in 1885 and 1894. The economic categories he employed were those of the classical British economics of David Ricardo; but Marx used them in accordance with his dialectical method to argue that bourgeois society, like every social organism, must follow its inevitable path of development. Through the working of such immanent tendencies as the declining rate of profit, capitalism would die and be replaced by another, higher, society. The most memorable pages in *Das Kapital* are the descriptive passages, culled from Parliamentary Blue Books, on the misery of the English working class. Marx believed that this misery would increase, while at the same time the monopoly of capital would become a fetter upon production until finally "the knell of capitalist private property sounds. The expropriators are expropriated."

Marx never claimed to have discovered the existence of classes and class struggles in modern society. "Bourgeois" historians, he acknowledged, had described them long before he had. He did claim, however, to have proved that each phase in the development of production was associated with a corresponding class structure and that the struggle of classes led necessarily to the dictatorship of the proletariat, ushering in the advent of a classless society. Marx took up the very different versions of socialism current in the early 19th century and welded them together into a doctrine that continued to be the dominant version of socialism for half a century after his death. His emphasis on the influence of economic structure on historical development has proved to be of lasting significance.

The dialectical model

Although Marx stressed economic issues in his writings, his major impact has been in the fields of sociology and history. Marx's most important contribution to sociological theory was his general mode of analysis, the "dialectical" model, which regards every social system as having within it immanent forces that give rise to "contradictions" (disequilibria) that can be resolved only by a new social system. Neo-Marxists, who no longer accept the economic reasoning in *Das Kapital,* are still guided by this model in their approach to capitalist society. In this sense, Marx's mode of analysis, like those of Thomas Malthus, Herbert Spencer, or Vilfredo Pareto, has become one of the theoretical structures that are the heritage of the social scientist. (L.S.F./D.T.McL.)

Marxism

The term Marxism is used in a number of different ways. In its most essential meaning it refers to the thought of Karl Marx but is usually extended to include that of his friend and collaborator Friedrich Engels. There is also Marxism as it has been understood and practiced by the various socialist movements, particularly before 1914. Then there is Soviet Marxism as worked out by Lenin and modified by Stalin, which under the name of Marxism-Leninism became the doctrine of the communist parties set up after the Russian Revolution. Offshoots of this include Marxism as interpreted by the anti-Stalinist Leon Trotsky and his followers, Mao Zedong's (Mao Tse-tung's) Chinese variant of Marxism-Leninism, and various Third World Marxisms. There are also the post-World War II nondogmatic Marxisms that have modified Marx's thought with borrowings from modern philosophies, principally from those of Edmund Husserl and Martin Heidegger but also from Sigmund Freud and others.

THE THOUGHT OF KARL MARX

The written work of Marx cannot be reduced to a philosophy, much less to a philosophical system. The whole of his work is a radical critique of philosophy, especially of Hegel's idealist system and of the philosophies of the left and right post-Hegelians. It is not, however, a mere denial of those philosophies. Marx declared that philosophy must become reality. One could no longer be content with interpreting the world; one must be concerned with transforming it, which meant transforming both the world itself and men's consciousness of it. This, in turn, required a critique of experience together with a critique of ideas. In fact, Marx believed that all knowledge involved a critique of ideas. He was not an empiricist. Rather, his work teems with concepts (appropriation, alienation, praxis, creative labour, value, etc.) that he had inherited from earlier philosophers and economists, including Hegel, Johann Fichte, Kant, Adam Smith, David Ricardo, and John Stuart Mill. What uniquely characterizes the thought of Marx is that, instead of making abstract affirmations about a whole group of problems such as man, knowledge, matter, and nature, he examines each problem in its dynamic relation to the others and, above all, tries to relate them to historical, social, political, and economic realities.

Historical materialism. In 1859, in the preface to his *Contribution to the Critique of Political Economy,* Marx wrote that the hypothesis that had served him as the basis for his analysis of society could be briefly formulated as follows:

Economic foundation of society

> In the social production that men carry on, they enter into definite relations that are indispensable and independent of their will, relations of production which correspond to a definite stage of development of their material forces of production. The sum total of these relations of production constitutes the economic structure of society, the real foundation, on which rises a legal and political superstructure, and to which correspond definite forms of social consciousness. The mode of production in material life determines the general character of the social, political, and intellectual processes of life. It is not the consciousness of men which determines their existence; it is on the contrary their social existence which determines their consciousness.

Raised to the level of historical law, this hypothesis was subsequently called historical materialism. Marx applied it to capitalist society, both in *The Communist Manifesto* and *Das Kapital* and in other writings. Although Marx reflected upon his working hypothesis for many years, he did not formulate it in a very exact manner: different expressions served him for identical realities. If one takes the text literally, social reality is structured in the following way:

1. Underlying everything as the real basis of society is the economic structure (what in late 20th-century language is sometimes called the infrastructure). This structure includes (a) the "material forces of production," that is, the labour and means of production, and (b) the overall "relations of production," or the social and political arrangements that regulate production and distribution. Although Marx stated that there is a correspondence between the "material forces" of production and the indispensable "relations" of production, he never made himself clear on the nature of the correspondence, a fact that was to be the source of differing interpretations among his later followers.

2. Above the economic structure rises the superstructure consisting of legal and political "forms of social consciousness" that correspond to the economic structure. Marx says nothing about the nature of this correspondence between ideological forms and economic structure, except that through the ideological forms men become conscious of the conflict within the economic structure between the material forces of production and the existing relations of production expressed in the legal property relations. In other words, "The sum total of the forces of production accessible to men determines the condition of society" and is at the base of society. "The social structure and the state issue continually from the life processes of definite individuals . . . as they are *in reality,* that is acting and materially producing." The political relations that men establish among themselves are dependent on material production, as are the legal relations. This foundation of the social on the economic is not an incidental point: it colours Marx's whole analysis. It is found in *Das Kapital* as well as in *The German Ideology* and the *Economic and Philosophic Manuscripts of 1844.*

Analysis of society. To go directly to the heart of the work of Marx, one must focus on his concrete program for man. This is just as important for an understanding of Marx as are *The Communist Manifesto* and *Das Kapital.* Marx's interpretation of man begins with human need. "Man," he wrote in the *Economic and Philosophic Manuscripts of 1844,*

Man as a natural being

> is first of all a *natural being.* As a natural being and a living natural being, he is endowed on the one hand with *natural powers, vital powers* . . . ; these powers exist in him as aptitudes, instincts. On the other hand, as an objective, natural, physical, sensitive being, he is a *suffering,* dependent and limited being . . . , that is, the *objects* of his instincts exist outside him, independent of him, but are the objects of his *need,* indispensable and essential for the realization and confirmation of his substantial powers.

The point of departure of human history is therefore living man, who seeks to satisfy certain primary needs. "The first historical fact is the production of the means to satisfy these needs." This satisfaction, in turn, opens the way for new needs. Human activity is thus essentially a struggle with nature that must furnish man with the means of satisfying his needs: drink, food, clothing, the development of his powers and then of his intellectual and artistic abilities. In this undertaking, man discovers himself as a productive being who humanizes himself by his labour. Furthermore, man humanizes nature while he naturalizes himself. By his creative activity, by his labour, he realizes his identity with the nature that he masters, while at the same time he achieves free consciousness. Born of nature man becomes fully human by opposing it. Becoming aware in his struggle against nature of what separates him from it, man finds the conditions of his fulfillment, of the realization of his true stature. The dawning of consciousness is inseparable from struggle. By appropriating all the creative energies, he discovers that "all that is called history is nothing else than the process of creating man through human labour, the becoming of nature for man. Man has thus evident and irrefutable proof of his own creation by himself." Understood in its universal dimension, human activity reveals that "for man, man is the supreme being." It is thus vain to speak of God, creation, and metaphysical problems. Fully naturalized, man is sufficient unto himself: he has recaptured the fullness of man in his full liberty.

Man as an alienated being

Living in a capitalist society, however, man is not truly free. He is an alienated being; he is not at home in his world. The idea of alienation, which Marx takes from Hegel and Feuerbach, plays a fundamental role in the whole of his written work, starting with the writings of his youth and continuing through *Das Kapital.* In the *Economic and Philosophic Manuscripts* the alienation of labour is seen to spring from the fact that the more the worker produces the less he has to consume, and the more values he creates the more he devalues himself, because his product and his labour are estranged from him. The life of the worker depends on things that he has created but that are not his, so that, instead of finding his rightful existence through his labour, he loses it in this world of things that are external to him: no work, no pay. Under these conditions, labour denies the fullness of concrete man. "The generic being (*Gattungwesen*) of man, nature as well as his intellectual faculties, is transformed into a being which is alien to him, into a *means of his individual existence.*" Nature, his body, his spiritual essence become alien to him. "Man is made alien to man." When carried to its highest stage of development, private property becomes "the product of alienated labour . . . the *means* by which labour alienates itself (and) the realization of this alienation." It is also at the same time "the tangible material expression of *alienated human* life."

Although there is no evidence that Marx ever disclaimed this anthropological analysis of alienated labour, starting with *The German Ideology,* the historical, social, and economic causes of the alienation of labour are given increasing emphasis, especially in *Das Kapital.* Alienated labour is seen as the consequence of market product, the division of labour, and the division of society into antagonistic classes. As producers in society, men create goods only by their labour. These goods are exchangeable. Their value is the average amount of social labour spent to produce them.

Economic alienation

The alienation of the worker takes on its full dimension in that system of market production in which part of the value of the goods produced by the worker is taken away from him and transformed into surplus value, which the capitalist privately appropriates. Market production also intensifies the alienation of labour by encouraging specialization, piecework, and the setting up of large enterprises. Thus the labour power of the worker is used along with that of others in a combination whose significance he is ignorant of, both individually and socially. In thus losing their quality as human products, the products of labour become fetishes, that is, alien and oppressive realities to which both the man who possesses them privately and the man who is deprived of them submit themselves. In the market economy, this submission to things is obscured by the fact that the exchange of goods is expressed in money.

This fundamental economic alienation is accompanied by secondary political and ideological alienations, which offer a distorted representation of and an illusory justification of a world in which the relations of men with one another are also distorted. The ideas that men form are closely bound up with their material activity and their material relations: "The act of making representations, of thinking, the spiritual intercourse of men, seem to be the direct emanation of their material relations." This is true of all human activity: political, intellectual, or spiritual. "Men produce their representations and their ideas, but it is as living men, men acting as they are determined by a definite development of their powers of production." Law, morality, metaphysics, and religion do not have a history of their own. "Men developing their material production modify together with their real existence their ways of thinking and the products of their ways of thinking." In other words, "It is not consciousness which determines existence, it is existence which determines consciousness."

In bourgeois, capitalist society man is divided into political citizen and economic man. This duality represents man's political alienation, which is further intensified by the functioning of the bourgeois state. From this study of society at the beginning of the 19th century, Marx came to see the state as the instrument through which the propertied class dominated other classes.

Ideological alienation, for Marx, takes different forms,

appearing in economic, philosophical, and legal theories. Marx undertook a lengthy critique of the first in *Das Kapital* and of the second in *The German Ideology*. But ideological alienation expresses itself supremely in religion. Taking up the ideas about religion that were current in left post-Hegelian circles, together with the thought of Feuerbach, Marx considered religion to be a product of man's consciousness. It is a reflection of the situation of a man who "either has not conquered himself or has already lost himself again" (man in the world of private property). It is "an opium for the people." Unlike Feuerbach, Marx believed that religion would disappear only with changes in society.

Analysis of the economy. Marx analyzed the market economy system in *Das Kapital*. In this work he borrows most of the categories of the classical English economists Smith and Ricardo but adapts them and introduces new concepts such as that of surplus value. One of the distinguishing marks of *Das Kapital* is that in it Marx studies the economy as a whole and not in one or another of its aspects. His analysis is based on the idea that man is a productive being and that all economic value comes from human labour. The system he analyzes is principally that of mid-19th-century England. It is a system of private enterprise and competition that arose in the 16th century from the development of sea routes, international trade, and colonialism. Its rise had been facilitated by changes in the forces of production (the division of labour and the concentration of workshops), the adoption of mechanization, and technical progress. The wealth of the societies that brought this economy into play had been acquired through an "enormous accumulation of commodities." Marx therefore begins with the study of this accumulation, analyzing the unequal exchanges that take place in the market.

Theory of surplus value

According to Marx, if the capitalist advances funds to buy cotton yarn with which to produce fabrics and sells the product for a larger sum than he paid, he is able to invest the difference in additional production. "Not only is the value advance kept in circulation, but it changes in its magnitude, adds a plus to itself, makes itself worth more, and it is this movement that transforms it into capital." The transformation, to Marx, is possible only because the capitalist has appropriated the means of production, including the labour power of the worker. Now labour power produces more than it is worth. The value of labour power is determined by the amount of labour necessary for its reproduction or, in other words, by the amount needed for the worker to subsist and beget children. But in the hands of the capitalist the labour power employed in the course of a day produces more than the value of the sustenance required by the worker and his family. The difference between the two values is appropriated by the capitalist, and it corresponds exactly to the surplus value realized by capitalists in the market. Marx is not concerned with whether in capitalist society there are sources of surplus value other than the exploitation of human labour—a fact pointed out by Joseph Schumpeter (*Capitalism, Socialism, and Democracy*). He remains content with emphasizing this primary source:

> Surplus value is produced by the employment of labour power. Capital buys the labour power and pays the wages for it. By means of his work the labourer creates new value which does not belong to him, but to the capitalist. He must work a certain time merely in order to reproduce the equivalent value of his wages. But when this equivalent value has been returned, he does not cease work, but continues to do so for some further hours. The new value which he produces during this extra time, and which exceeds in consequence the amount of his wage, constitutes surplus value.

The crises of capitalism

Throughout his analysis, Marx argues that the development of capitalism is accompanied by increasing contradictions. For example, the introduction of machinery is profitable to the individual capitalist because it enables him to produce more goods at a lower cost, but new techniques are soon taken up by his competitors. The outlay for machinery grows faster than the outlay for wages. Since only labour can produce the surplus value from which profit is derived, this means that the capitalist's rate of profit on his total outlay tends to decline. Along with the declining rate of profit goes an increase in unemployment. Thus, the equilibrium of the system is precarious, subject as it is to the internal pressures resulting from its own development. Crises shake it at regular intervals, preludes to the general crisis that will sweep it away. This instability is increased by the formation of a reserve army of workers, both factory workers and peasants, whose pauperization keeps increasing. "Capitalist production develops the technique and the combination of the process of social production only by exhausting at the same time the two sources from which all wealth springs: the earth and the worker." According to the Marxist dialectic, these fundamental contradictions can only be resolved by a change from capitalism to a new system.

Class struggle. Marx inherited the ideas of class and class struggle from Utopian socialism and the theories of Saint-Simon. These had been given substance by the writings of French historians such as Adolphe Thiers and François Guizot on the French Revolution of 1789. But unlike the French historians, Marx made class struggle the central fact of social evolution. "The history of all hitherto existing human society is the history of class struggles."

In Marx's view, the dialectical nature of history is expressed in class struggle. With the development of capitalism, the class struggle takes an acute form. Two basic classes, around which other less important classes are grouped, oppose each other in the capitalist system: the owners of the means of production, or bourgeoisie, and the workers, or proletariat. "The bourgeoisie produces its own grave-diggers. The fall of the bourgeoisie and the victory of the proletariat are equally inevitable" (*The Communist Manifesto*) because

> the bourgeois relations of production are the last contradictory form of the process of social production, contradictory not in the sense of an individual contradiction, but of a contradiction that is born of the conditions of social existence of individuals; however, the forces of production which develop in the midst of bourgeois society create at the same time the material conditions for resolving this contradiction. With this social development the prehistory of human society ends.

When man has become aware of his loss, of his alienation, as a universal nonhuman situation, it will be possible for him to proceed to a radical transformation of his situation by a revolution. This revolution will be the prelude to the establishment of communism and the reign of liberty reconquered. "In the place of the old bourgeois society with its classes and its class antagonisms, there will be an association in which the free development of each is the condition for the free development of all."

Two views of revolution

But for Marx there are two views of revolution. One is that of a final conflagration, "a *violent* suppression of the old conditions of production," which occurs when the opposition between bourgeoisie and proletariat has been carried to its extreme point. This conception is set forth in a manner inspired by the Hegelian dialectic of the master and the slave, in *The Holy Family*. The other conception is that of a permanent revolution involving a provisional coalition between the proletariat and the petty bourgeoisie rebelling against a capitalism that is only superficially united. Once a majority has been won to the coalition, an unofficial proletarian authority constitutes itself alongside the revolutionary bourgeois authority. Its mission is the political and revolutionary education of the proletariat, gradually assuring the transfer of legal power from the revolutionary bourgeoisie to the revolutionary proletariat.

If one reads *The Communist Manifesto* carefully one discovers inconsistencies that indicate that Marx had not reconciled the concepts of catastrophic and of permanent revolution. Moreover, Marx never analyzed classes as specific groups of men opposing other groups of men. Depending on the writings and the periods, the number of classes varies; and unfortunately the pen fell from Marx's hand at the moment when, in *Das Kapital* (vol. 3), he was about to take up the question. Reading *Das Kapital*, one is furthermore left with an ambiguous impression with regard to the destruction of capitalism: will it be the result of the "general crisis" that Marx expects, or of the action of the conscious proletariat, or of both at once?

The contributions of Engels. Engels became a communist in 1842 and discovered the proletariat of England when he took over the management of the Manchester factory belonging to his father's cotton firm. In 1844, the year he began his close association and friendship with Marx, Engels was finishing his "Umrisse zu einer Kritik der Nationalökonomie" ("Outline of a Critique of Political Economy")—a critique of Smith, Ricardo, Mill, and J.B. Say. This remarkable study contained in seminal form the critique that Marx was to make of bourgeois political economy in *Das Kapital.* During the first years of his stay in Manchester, Engels observed carefully the life of the workers of that great industrial centre and described it in *Die Lage der arbeitenden Klassen in England* (*The Condition of the Working Class in England*), published in 1845 in Leipzig. This work was an analysis of the evolution of industrial capitalism and its social consequences. He collaborated with Marx in the writing of *The Holy Family, The German Ideology,* and *The Communist Manifesto.* The correspondence between them is of fundamental importance for the student of *Das Kapital,* for it shows how Engels contributed by furnishing Marx with a great amount of technical and economic data and by criticizing the successive drafts. This collaboration lasted until Marx's death and was carried on posthumously with the publication of the manuscripts left by Marx, which Engels edited, forming volumes 2 and 3 of *Das Kapital.* He also wrote various articles on Marx's work.

In response to criticism of Marx's ideas by a socialist named Eugen Dühring, Engels published several articles that were collected under the title *Herr Eugen Dührings Umwälzung der Wissenschaft,* which appeared in 1878 (*Herr Eugen Dühring's Revolution in Science* [*Anti-Dühring*]), and an unfinished work, *Dialektik und Natur* (1927; *Dialectics of Nature*), which he had begun around 1875–76. The importance of these writings to the subsequent development of Marxism can be seen from Lenin's observation that Engels "developed, in a clear and often polemical style, the most general scientific questions and the different phenomena of the past and present according to the materialist understanding of history and the economic theory of Karl Marx." But Engels was driven to simplify problems with a view to being pedagogical; he tended to schematize and systematize things as if the fundamental questions were settled. The connections that he thus established between some of Marx's governing ideas and some of the scientific ideas of his age gave rise to the notion that there is a complete Marxist philosophy. The idea was to play a significant role in the transition of Marxism from a "critique of daily life" to an integrated doctrine in which philosophy, history, and the sciences are fused.

Engels' critique of Dühring

Anti-Dühring is of fundamental importance for it constitutes the link between Marx and certain forms of modern Marxism. It contains three parts: Philosophy, Political Economy, and Socialism. In the first, Engels attempts to establish that the natural sciences and even mathematics are dialectical, in the sense that observable reality is dialectical: the dialectical method of analysis and thought is imposed on men by the material forces with which they deal. It is thus rightly applied to the study of history and human society. "Motion, in effect, is the mode of existence of matter," Engels writes. In using materialistic dialectic to make a critique of Dühring's thesis, according to which political forces prevail over all the rest in the molding of history, Engels provides a good illustration of the materialistic idea of history, which puts the stress on the prime role of economic factors as driving forces in history. The other chapters of the section Political Economy form a very readable introduction to the principal economic ideas of Marx: value (simple and complex), labour, capital, and surplus value. The section Socialism starts by formulating anew the critique of the capitalist system as it was made in *Das Kapital.* At the end of the chapters devoted to production, distribution, the state, the family, and education, Engels outlines what the socialist society will be like, a society in which the notion of value has no longer anything to do with the distribution of the goods produced because all labour "becomes at once and directly social labour," and the amount of social labour that every product contains no longer needs to be ascertained by "a detour." A production plan will coordinate the economy. The division of labour and the separation of town and country will disappear with the "suppression of the capitalist character of modern industry." Thanks to the plan, industry will be located throughout the country in the collective interest, and thus the opposition between town and country will disappear—to the profit of both industry and agriculture. Finally, after the liberation of man from the condition of servitude in which the capitalist mode of production holds him, the state will also be abolished and religion will disappear by "natural death."

One of the most remarkable features of *Anti-Dühring* is the insistence with which Engels refuses to base socialism on absolute values. He admits only relative values, linked to historical, economic, and social conditions. Socialism cannot possibly be based on ethical principles: each epoch can only successfully carry out that of which it is capable. Marx had written this in his preface of 1859.

GERMAN MARXISM AFTER ENGELS

The work of Kautsky and Bernstein. The theoretical leadership after Engels was taken by Karl Kautsky, editor of the official organ of the German Social Democratic Party, *Die Neue Zeit.* He wrote *Karl Marx' ökonomische Lehren* (1887; *The Economic Doctrines of Karl Marx*), in which the work of Marx is presented as essentially an economic theory. Kautsky reduced the ideas of Marx and Marxist historical dialectic to a kind of evolutionism. He laid stress on the increasing pauperization of the working class and on the increasing degree of capitalist concentration. While opposing all compromise with the bourgeois state, he accepted the contention that the socialist movement should support laws benefiting the workers provided that they did not reinforce the power of the state. Rejecting the idea of an alliance between the working class and the peasantry, he believed that the overthrow of the capitalist state and the acquisition of political power by the working class could be realized in a peaceful way, without upsetting the existing structures. As an internationalist he supported peace, rejecting war and violence. For him, war was a product of capitalism. Such were the main features of "orthodox" German Marxism at the time when the "revisionist" theories of Eduard Bernstein appeared.

Doctrinal disputes

Bernstein created a great controversy with articles that he wrote in 1896 for *Die Neue Zeit,* arguing that Marxism needed to be revised. His divergence widened with the publication in 1899 of *Die Voraussetzungen des Sozialismus und die Aufgaben der Sozialdemokratie* (*Evolutionary Socialism*), to which rejoinders were made by Kautsky in *Bernstein und das Sozialdemokratische Programm: Eine Antikritik* (1899; "Bernstein and the Social Democratic Program") and the Polish-born Marxist Rosa Luxemburg in *Sozialreform oder Revolution* (*Reform or Revolution*), both in 1899. Bernstein focused first of all upon the labour theory of value. Along with the economists of his time he considered it outdated, both in the form expounded by British classical economists and as set forth in *Das Kapital.* He argued, moreover, that class struggle was becoming less rather than more intense, for concentration was not accelerating in industry as Marx had forecast, and in agricultureit was notincreasing at all. Bernstein demonstrated this on the basis of German, Dutch, and English statistical data. He also argued that cartels and business syndicates were smoothing the evolution of capitalism, a fact that cast doubt on the validity of Marx's theory of capitalistic crises. Arguing that quite a few of Marx's theories were not scientifically based, Bernstein blamed the Hegelian and Ricardian structure of Marx's work for his failure to take sufficient account of observable reality.

To this, Kautsky replied that, with the development of capitalism, agriculture was becoming a sector more and more dependent on industry, and that in addition an industrialization of agriculture was taking place. Luxemburg took the position that the contradictions of capitalism did not cease to grow with the progress of finance capitalism and the exploitation of the colonies, and that these contradictions were leading to a war that would give the

proletariat its opportunity to assume power by revolutionary means.

The radicals. One of the most divisive questions was that of war and peace. This was brought to the fore at the outbreak of World War I, when Social Democratic deputies in the German Reichstag voted for the financing of the war. Among German Marxists who opposed the war were Karl Liebknecht and Luxemburg. Liebknecht was imprisoned in 1916 for agitating against the war. On his release in 1918 he took the leadership of the Spartacist movement, which was later to become the Communist Party of Germany. Luxemburg had also been arrested for her antimilitary activities. In addition to her articles, signed Junius, in which she debated with Lenin on the subject of World War I and the attitude of the Marxists toward it (published in 1916 as *Die Krise der Sozialdemokratie* [*The Crisis in the German Social-Democracy*]), she is known for her book *Die Akkumulation des Kapitals* (1913; *The Accumulation of Capital*). In this work she returned to Marx's economic analysis of capitalism, in particular the accumulation of capital as expounded in volume 2 of *Das Kapital*. There she found a contradiction that had until then been unnoticed: Marx's scheme seems to imply that the development of capitalism can be indefinite, though elsewhere he sees the contradictions of the system as bringing about increasingly violent economic crises that will inevitably sweep capitalism away. Luxemburg concluded that Marx's scheme is oversimplified and assumes a universe made up entirely of capitalists and workers. If increases in productivity are taken into account, she asserted, balance between the two sectors becomes impossible; in order to keep expanding, capitalists must find new markets in noncapitalist spheres, either among peasants and artisans or in colonies and underdeveloped countries. Capitalism will collapse only when exploitation of the world outside it (the peasantry, colonies, etc.) has reached a limit. This conclusion has been the subject of passionate controversies.

Karl Liebknecht and Rosa Luxemburg

The Austrians. The Austrian school came into being when Austrian socialists started publishing their works independently of the Germans; it can be dated from either 1904 (beginning of the *Marx-Studien* collection) or 1907 (publication of the magazine *Der Kampf*). The most important members of the school were Max Adler, Karl Renner, Rudolf Hilferding, Gustav Eckstein, Friedrich Adler, and Otto Bauer. The most eminent was Bauer, a brilliant theoretician whose *Die Nationalitätenfrage und die Sozialdemokratie* (1906; "The Nationalities Question and the Social Democracy") was critically reviewed by Lenin. In this work he dealt with the problem of nationalities in the light of the experience of the Austro-Hungarian Empire. He favoured the self-determination of peoples and emphasized the cultural elements in the concept of nationhood. Hilferding was finance minister of the German Republic after World War I in the Cabinets of the Social Democrats Gustav Stresemann (1923) and Hermann Müller (1928). He is known especially for his work *Das Finanzkapital* (1910), in which he maintained that capitalism had come under the control of banks and industrial monopolies. The growth of national competition and tariff barriers, he believed, had led to economic warfare abroad. Hilferding's ideas strongly influenced Lenin, who analyzed them in *Imperialism, the Highest Stage of Capitalism* (1916).

RUSSIAN AND SOVIET MARXISM

Das Kapital was translated into Russian in 1872. Marx kept up more or less steady relations with the Russian socialists and took an interest in the economic and social conditions of the tsarist empire. The man who originally introduced Marxism into Russia was Georgi Plekhanov, but the man who adapted Marxism to Russian conditions was Lenin.

Lenin's adaptation of Marxism

Lenin. Vladimir Ilich Ulyanov, or Lenin, was born in 1870 at Simbirsk. He entered the University of Kazan to study law but was expelled the same year for participating in student agitation. In 1893 he settled in St. Petersburg and became actively involved with the revolutionary workers. With his pamphlet *What Is To Be Done?* (1902), he specified the theoretical principles and organization of a Marxist party as he thought it should be constituted. He took part in the second Congress of the Russian Social-Democratic Workers' Party, which was held in Brussels and London (1903), and induced the majority of the Congress members to adopt his views. Two factions formed at the Congress: the Bolshevik (from the Russian word for "larger") with Lenin as the leader and the Menshevik (from the Russian word for "smaller") with Julius Martov at the head. The former wanted a restricted party of militants and advocated the dictatorship of the proletariat. The latter wanted a wide-open proletarian party, collaboration with the liberals, and a democratic constitution for Russia. In his pamphlet *One Step Forward, Two Steps Back* (1904), Lenin compared the organizational principles of the Bolsheviks to those of the Mensheviks. After the failure of the 1905 Russian revolution, he drew positive lessons for the future in *Two Tactics of Social Democracy in the Democratic Revolution*. He fiercely attacked the influence of Kantian philosophy on German and Russian Marxism in *Materialism and Empirio-criticism* (1908). In 1912 at the Prague Conference the Bolsheviks constituted themselves as an independent party. During World War I Lenin resided in Switzerland, where he studied Hegel's *Science of Logic* and the development of capitalism and carried on debates with Marxists like Rosa Luxemburg on the meaning of the war and the right of nations to self-determination. In 1915 at Zimmerwald, and in 1916 at Kiental, he organized two international socialist conferences to fight against the war. Immediately after the February 1917 revolution he returned to Russia, and in October the Bolshevik coup brought him to power.

The situation of Russia and the Russian revolutionary movement at the end of the 19th century and the beginning of the 20th led Lenin to diverge, in the course of his development and his analyses, from the positions both of "orthodox Marxism" and of "revisionism." He rediscovered the original thought of Marx by a careful study of his works, in particular *Das Kapital* and *The Holy Family*. He saw Marxism as a practical affair and tried to go beyond the accepted formulas to plan political action that would come to grips with the surrounding world.

A plan of political action

As early as 1894, in his populist study *The Friends of the People*, Lenin took up Marx's distinction between the "material social relations" of men and their "ideological social relations." In Lenin's eyes the importance of *Das Kapital* was that "while *explaining* the structure and the development of the social formation seen *exclusively* in terms of its relations of production, (Marx) has nevertheless everywhere and always analyzed the superstructure which corresponds to these relations of production." In *The Development of Russian Capitalism* (1897–99) Lenin sought to apply Marx's analysis by showing the growing role of capital, in particular commercial capital, in the exploitation of the workers in the factories and the large-scale expropriation of the peasants. It was thus possible to apply to Russia the models developed by Marx for western Europe. At the same time Lenin did not lose sight of the importance of the peasant in Russian society. Although a disciple of Marx, he did not believe that he had only to repeat Marx's conclusions. He wrote:

> We do not consider the theory of Marx to be a complete, immutable whole. We think on the contrary that this theory has only laid the cornerstone of the science, a science which socialists must further develop in all directions if they do not want to let themselves be overtaken by life. We think that, for the Russian socialists, an independent elaboration of the theory is particularly necessary.

Lenin laid great stress upon the dialectical method. In his early writings he defined the dialectic as "nothing more nor less than the method of sociology, which sees society as a living organism, in perpetual development (and not as something mechanically assembled and thus allowing all sorts of arbitrary combinations of the various social elements) . . . " (*The Friends of the People*, 1894). After having studied Hegel toward the end of 1914, he took a more activist view. Dialectic is not only evolution; it is praxis, leading from activity to reflection and from reflection to action.

The dictatorship of the proletariat. Lenin also put much emphasis on the leading role of the party. As early as 1902 he was concerned with the need for a cohesive party with a correct doctrine, adapted to the exigencies of the period, which would be a motive force among the masses, helping to bring them to an awareness of their real situation. In *What Is To Be Done?* he called for a party of professional revolutionaries, disciplined and directed, capable of defeating the police; its aim should be to establish the dictatorship of the proletariat. In order to do this, he wrote in *Two Tactics of Social-Democracy in the Democratic Revolution,* it was necessary "to subject the insurrection of the proletarian and *non-proletarian* masses to our influence, to our direction, to use it in our best interests." But this was not possible without a doctrine: "Without revolutionary theory, no revolutionary movement." On the eve of the revolution of October 1917, in *The State and Revolution* he set forth the conditions for the dictatorship of the proletariat and the suppression of the capitalist state.

Lenin assigned major importance to the peasantry in formulating his program. It would be a serious error, he held, for the Russian revolutionary workers' movement to neglect the peasants. Even though it was clear that the industrial proletariat constituted the vanguard of the revolution, the discontent of the peasantry could be oriented in a direction favourable to the revolution by placing among the goals of the party the seizure of privately owned land. As early as 1903, at the third congress of the party, he secured a resolution to this effect. Thereafter, the dictatorship of the proletariat became the dictatorship of the proletariat and the peasantry. In 1917 he encouraged the peasants to seize land long before the approval of agrarian reform by the Constituent Assembly.

Among Lenin's legacies to Soviet Marxism was one that proved to be injurious to the party. This was the decision taken at his behest by the 10th congress of the party in the spring of 1921, while the sailors were rebelling at Kronstadt and the peasants were growing restless in the countryside, to forbid all factions, all factional activity, and all opposition political platforms within the party. This decision had grave consequences in later years when Stalin used it against his opponents.

Stalin. It is Joseph Stalin who codified the body of ideas that, under the name of Marxism-Leninism, has constituted the official doctrine of the Soviet and eastern European communist parties. Stalin was a man of action in a slightly different sense than was Lenin. Gradually taking over power after Lenin's death in 1924, he pursued the development of the Soviet Union with great vigour. By practicing Marxism, he assimilated it, at the same time simplifying it. Stalin's Marxism-Leninism rests on the dialectic of Hegel, as set forth in *A Short History of the Communist Party of the Soviet Union* (1938), and on a materialism that can be considered roughly identical to that of Feuerbach. His work *Problems of Leninism,* which appeared in 11 editions during his lifetime, sets forth an ideology of power and activism that rides roughshod over the more nuanced approach of Lenin.

Stalin and dialectical materialism

Soviet dialectical materialism can be reduced to four laws: (1) History is a dialectical development. It proceeds by successive phases that supersede one another. These phases are not separate, any more than birth, growth, and death are separate. Though it is true that phase B necessarily negates phase A, it remains that phase B was already contained in phase A and was initiated by it. The dialectic does not regard nature as an accidental accumulation of objects, of isolated and independent phenomena, but as a unified, coherent whole. Furthermore, nature is perpetually in movement, in a state of unceasing renewal and development, in which there is always something being born and developing and something disintegrating and disappearing. (2) Evolution takes place in leaps, not gradually. (3) Contradictions must be made manifest. All phenomena contain in themselves contradictory elements. "Dialectic starts from the point of view that objects and natural phenomena imply internal contradictions, because they all have a positive and a negative side." These contradictory elements are in perpetual struggle: it is this struggle that is the "internal content of the process of development," according to Stalin. (4) The law of this development is economic. All other contradictions are rooted in the basic economic relationship. A given epoch is entirely determined by the relations of production existing among men. They are social relations; relations of collaboration or mutual aid, relations of domination or submission; and finally, transitory relations that characterize a period of passage from one system to another. "The history of the development of society is, above all, the history of the development of production, the history of the modes of production which succeed one another through the centuries."

From these principles may be drawn the following inferences, essential for penetrating the workings of Marxist-Leninist thought and its application. No natural phenomenon, no historical or social situation, no political fact, can be considered independently of the other facts or phenomena that surround it; it is set within a whole. Since movement is the essential fact, one must distinguish between what is beginning to decay and what is being born and developing. Since the process of development takes place by leaps, one passes suddenly from a succession of slow quantitative changes to a radical qualitative change. In the social or political realm, these sudden qualitative changes are revolutions, carried out by the oppressed classes. One must follow a frankly proletarian-class policy that exposes the contradictions of the capitalist system. A reformist policy makes no sense. Consequently (1) nothing can be judged from the point of view of "eternal justice" or any other preconceived notion and (2) no social system is immutable. To be effective, one must not base one's action on social strata that are no longer developing, even if they represent for the moment the dominant force, but on those that are developing.

Differences between Marx's ideas and Stalin's

Stalin's materialist and historical dialectic differs sharply from the perspective of Karl Marx. In *The Communist Manifesto* Marx applied the materialist dialectic to the social and political life of his time. In the chapter entitled "Bourgeois and Proletarians," he studied the process of the growth of the revolutionary bourgeoisie within feudal society, then the genesis and the growth of the proletariat within capitalism, placing the emphasis on the struggle between antagonistic classes. To be sure, he connected social evolution with the development of the forces of production. What counted for him, however, was not only the struggle but also the birth of consciousness among the proletariat. "As to the final victory of the propositions put forth in the *Manifesto,* Marx expected it to come primarily from the intellectual development of the working class, necessarily the result of common action and discussion" (Engels, preface to the republication of *The Communist Manifesto,* May 1, 1890).

The result of Stalin's dialectic, however, was what he called revolution from above, a dictatorial policy to increase industrialization and collectivize agriculture based upon ruthless repression and a strong centralization of power. For Stalin what counted was the immediate goal, the practical result. The move was from a dialectic that emphasized both the objective and the subjective to one purely objective, or more exactly, objectivist. Human actions are to be judged not by taking account of the intentions of the actor and their place in a given historical web but only in terms of what they signify objectively at the end of the period considered.

Trotskyism. Alongside Marxism-Leninism as expounded in the former Soviet Union, there arose another point of view expressed by Stalin's opponent Leon Trotsky and his followers. Trotsky played a leading role in both the Russian Revolution of 1905 and that of 1917. After Lenin's death he fell out with Stalin. Their conflict turned largely upon questions of policy, both domestic and foreign. In the realm of ideas, Trotsky held that a revolution in a backward, rural country could be carried out only by the proletariat. Once in power the proletariat must carry out agrarian reform and undertake the accelerated development of the economy. The revolution must be a socialist one, involving the abolition of the private ownership of the means of production, or else it will fail.

But the revolution cannot be carried out in isolation, as Stalin maintained it could. The capitalist countries will try to destroy it; moreover, to succeed the revolution must be able to draw upon the industrial techniques of the developed countries. For these reasons the revolution must be worldwide and permanent, directed against the liberal and nationalist bourgeoisie of all countries and using local victories to advance the international struggle.

Tactically, Trotsky emphasized the necessity of finding or creating a revolutionary situation, of educating the working class in order to revolutionize it, of seeing that the party remained open to the various revolutionary tendencies and avoided becoming bureaucratized, and finally, when the time for insurrection comes, of organizing it according to a detailed plan.

VARIANTS OF MARXISM

Maoism. When the Chinese Communists took power in 1948, they brought with them a new kind of Marxism that came to be called Maoism after their leader Mao Zedong. The thought of Mao must always be seen against the changing revolutionary reality of China from 1930 onward. His thought was complex, a Marxist type of analysis combined with the permanent fundamentals of Chinese thought and culture.

One of its central elements has to do with the nature and role of contradictions in socialist society. For Mao, every society, including socialist (communist) society, contained "two different types of contradictions": (1) antagonistic contradictions—contradictions between us (the people) and our enemies (the Chinese bourgeoisie faithful), between the imperialist camp and the socialist camp, and so forth—which are resolved by revolution, and (2) nonantagonistic contradictions—between the government and the people under a socialist regime, between two groups within the Communist Party, between one section of the people and another under a communist regime, and so forth—which are resolved by vigorous fraternal criticism and self-criticism.

The notion of contradiction is specific to Mao's thought in that it differs from the conceptions of Marx or Lenin. For Mao, in effect, contradictions were at the same time universal and particular. In their universality, one must seek and discover what constitutes their particularity: every contradiction displays a particular character, depending on the nature of things and phenomena. Contradictions have alternating aspects—sometimes strongly marked, sometimes blurred. Some of these aspects are primary, others secondary. It is important to define them well, for if one fails to do so, the analysis of the social reality and the actions that follow from it will be mistaken. This is quite far from Stalinism and dogmatic Marxism-Leninism.

Mao's theory of permanent revolution

Another essential element of Mao's thought, which must be seen in the context of revolutionary China, is the notion of permanent revolution. It is an old idea advocated in different contexts by Marx, Lenin, and Trotsky but lacking, in Mao's formulation, the international dimension espoused by his predecessors. For Mao it followed from his ideas about the struggle of man against nature (held from 1938, at least); the campaigns for the rectification of thought (1942, 1951, 1952); and the necessity of struggling against bureaucracy, wastage, and corruption in a country of 600,000,000 to 700,000,000 inhabitants, where very old civilizations and cultures still permeated both the bourgeois classes and the peasantry, where bureaucracy was thoroughly entrenched, and where the previous society was extremely corrupt. It arose from Mao's conviction that the rhythm of the revolution must be accelerated. This conviction appeared in 1957 in his speeches and became manifest in 1958 in the "Great Leap Forward," followed in 1966 by the Cultural Revolution.

Mao's concept of permanent revolution rests upon the existence of nonantagonistic contradictions in the China of today and of tomorrow. Men must be mobilized into a permanent movement in order to carry forward the revolution and to prevent the ruling group from turning bourgeois (as he perceived it had in the Soviet Union). It is necessary to shape among the masses a new vision of the world by tearing them from their passivity and their century-old habits. This is the background of the Cultural Revolution that began in 1966, following previous campaigns but differing from them in its magnitude and, it would seem, in the mobilization of youth against the cadres of the party. In these campaigns Mao drew upon his past as a revolutionary Marxist peasant leader, from his life in the red military and peasant bases and among the Red Guards of Yen-an, seeking in his past experience ways to mobilize the whole Chinese population against the dangers—internal and external—that confronted it in the present.

The distinguishing characteristic of Maoism is that it represents a peasant type of Marxism, with a principally rural and military outlook. While basing himself on Marxism-Leninism, adapted to Chinese requirements, Mao was rooted in the peasant life from which he himself came, in the revolts against the warlords and the bureaucrats that have filled the history of China. By integrating this experience into a universal vision of history, Mao gave it a significance that flows beyond the provincial limits of China.

In his effort to remain close to the Chinese peasant masses, Mao drew upon an idea of nature and a symbolism found in popular Chinese Taoism, though transformed by his Marxism. It can be seen in his many poems, which were written in the classical Chinese style. This idea of nature is accompanied in his written political works by the Promethean idea of man struggling in a war against nature, a conception in his thought that goes back at least to 1938 and became more important after 1955 as the rhythm of the revolution accelerated.

Castroism

Marxism in Cuba. The Marxism of Fidel Castro expresses itself as a rejection of injustice in any form—political, economic, or social. In this sense it is related to the liberal democracy and Pan-Americanism of Simón Bolívar in Latin America during the 19th century. In its liberalism, Castro's early socialism resembled the various French socialisms of the first half of the 19th century. Only gradually did Castroism come to identify itself with Marxism-Leninism, although from the very beginning of the Cuban revolution Castro revealed his attachment to certain of Marx's ideas. Castro's Marxism rejects some of the tenets and practices of official Marxism-Leninism: it is outspoken against dogmatism, bureaucracy, and sectarianism. In one sense, Castroism is a Marxist-Leninist "heresy." It exalts the ethos of guerrilla revolution over party politics. At the same time it aims to apply a purer Marxism to the conditions of Cuba: alleged American imperialism, a single-crop economy, a low initial level of political and economic development. One may call it an attempt to realize a synthesis of Marxist ideas and the ideas of Bolívar.

In the ideological and political conflicts that divide the communist world, Castroism takes a more or less unengaged position. Castro is above all a nationalist and only after that a Marxist.

Marxism in the Third World. The development of Marxist variants in the Third World has been primarily influenced by the undeveloped industrial state and the former colonial status of the nations in question. In the traditional Marxist view the growth of capitalism is seen as a step necessary for the breakup of precapitalist peasant society and for the rise of the revolutionary proletariat class. Some theorists believe, however, that capitalism introduced by imperialist rather than indigenous powers sustains rather than destroys the feudal structure of peasant society and promotes underdevelopment because resources and surplus are usurped by the colonial powers. Furthermore, the revolutionary socialist movement becomes subordinate to that of national liberation, which violates Marx's theory of class struggle by uniting all indigenous classes in the common cause of anti-imperialism. For these reasons, many Third World countries have chosen to follow the Maoist model, with its emphasis on agrarian revolution against feudalism and imperialism, rather than the old Soviet one. Another alternative, one specific to the Third World, also exists. This policy bypasses capitalism and depends upon the established strength of other communist countries for support against imperialism.

Marxism in the West. There are two main forms of Marxism in the West: that of the traditional communist parties and the more diffuse "New Left" form, which has come to be known as "Western Marxism." In general, the success of western European communist parties had been hindered by their perceived allegiance to the old Soviet authority rather than their own countries; the secretive, bureaucratic form of organization they inherited from Lenin; the ease with which they became integrated into capitalist society; and their consequent fear of compromising their principles by sharing power with bourgeois parties. The Western parties basically adhered to the policies of Soviet Marxism until the 1970s, when they began to advocate Eurocommunism, a moderate version of communism that they felt would broaden their base of appeal beyond the working class and thus improve their chances for political success. As described by Enrico Berlinguer, Georges Marchais, and Santiago Carrillo, the leaders of the Italian, French, and Spanish communist parties, respectively, Eurocommunism favoured a peaceful, democratic approach to achieving socialism, encouraged making alliances with other political parties, guaranteed civil liberties, and renounced the central authority of the Soviet party. By the 1980s Eurocommunism had largely been abandoned as unsuccessful, and communist parties in advanced capitalist nations returned to orthodox Marxism-Leninism despite the concomitant problems.

Western Marxism, however, can be seen as a repudiation of Marxism-Leninism, although, when it was first formulated in the 1920s, its proponents believed they were loyal to the dominant Soviet Communist Party. Prominent figures in the evolution of Western Marxism include the central Europeans György Lukács, Karl Korsch, and Lucien Goldmann; Antonio Gramsci of Italy; the German theorists who constituted the Frankfurt school, especially Max Horkheimer, Theodor Adorno, Herbert Marcuse, and Jürgen Habermas; and Henri Lefebvre, Jean-Paul Sartre, and Maurice Merleau-Ponty of France.

Western Marxism

Western Marxism has been shaped primarily by the failure of the socialist revolution in the Western world. Western Marxists were concerned less with the actual political or economic practice of Marxism than with its philosophical interpretation, especially in relation to cultural and historical studies. In order to explain the inarguable success of capitalist society, they felt they needed to explore and understand non-Marxist approaches and all aspects of bourgeois culture. Eventually, they came to believe that traditional Marxism was not relevant to the reality of modern Western society.

Marx had predicted that revolution would succeed in Europe first, but, in fact, the Third World has proved more responsive. Orthodox Marxism also championed the technological achievements associated with capitalism, viewing them as essential to the progress of socialism. Experience showed the Western Marxists, however, that technology did not necessarily produce the crises Marx described and did not lead inevitably to revolution. In particular they disagreed with the idea, originally emphasized by Engels, that Marxism is an integrated, scientific doctrine that can be applied universally to nature; they viewed it as a critique of human life, not an objective, general science. Disillusioned by the terrorism of the Stalin era and the bureaucracy of the Communist Party system, they advocated the idea of government by workers' councils, which they believed would eliminate professional politicians and would more truly represent the interests of the working class. Later, when the working class appeared to them to be too well integrated into the capitalist system, the Western Marxists supported more anarchistic tactics. In general, their views are more in accord with those found in Marx's early, humanist writings rather than with his later, dogmatic interpretations.

Western Marxism has found support primarily among intellectuals rather than the working class, and orthodox Marxists have judged it impractical. Nevertheless, the Western Marxists' emphasis on Marx's social theory and their critical assessment of Marxist methodology and ideas have coloured the way even non-Marxists view the world.

(H.C./D.T.McL./Ed.)

MAJOR WORKS

Misère de la philosophie (1847; *The Poverty of Philosophy*, 1900); *Manifest der Kommunistischen Partei* (1848; *Manifesto of the Communists*, 1883); *Die Klassenkämpfe in Frankreich 1848 bis 1850* (1850; *The Class Struggles in France, 1848 to 1850*, 1924); *Der 18te Brumaire des Louis Napoleon* (1852; *The Eighteenth Brumaire of Louis Bonaparte*, 1898); *Zur Kritik der politischen Ökonomie* (1859; *A Contribution to the Critique of Political Economy*, 1904); and *Das Kapital* (vol. 1, 1867; vol. 2–3 published by Engels in 1885 and 1894; *Capital: A Critical Analysis of Capitalist Production*, vol. 1 trans. by Samuel Moore and Edward Aveling, 1886; vol. 2–3 trans. by Ernest Untermann, 1907 and 1909).

Recommended later translations of these works include *Manifesto of the Communist Party*, trans. by Samuel Moore (1888, reprinted 1952); *The Communist Manifesto of Karl Marx and Friedrich Engels*, with an introduction and explanatory notes by D. Ryazanoff, trans. by Eden Paul and Cedar Paul (1930); and *The Eighteenth Brumaire of Louis Bonaparte*, trans. by Eden Paul and Cedar Paul (1926). Selections from Marx's writings are available in the following: David McLellan (ed.), *Selected Writings* (1977); Robert C. Tucker (ed.), *The Marx-Engels Reader*, 2nd ed. (1978); and Jon Elster (ed.), *Karl Marx: A Reader* (1986).

A major English-language edition, *Karl Marx, Frederick Engels: Collected Works*, trans. by Richard Dixon *et al.* (1975–), is in progress. Planned to consist of 50 volumes and to include the correspondence, it is being prepared by an international editorial committee. Forty-one volumes had been published by 1992.

BIBLIOGRAPHY

Marx. The most comprehensive biography of Marx is DAVID MCLELLAN, *Karl Marx: His Life and Thought* (1973, reissued 1987). The classic biography of Marx, somewhat too partisan in his favour, is FRANZ MEHRING, *Karl Marx: The Story of His Life* (1935, reissued 1981; originally published in German, 1918). Marx's personal life is discussed in SAUL K. PADOVER, *Karl Marx, an Intimate Biography* (1978). JERROLD SEIGEL, *Marx's Fate: The Shape of a Life* (1978), is a psychological biography. YVONNE KAPP, *Eleanor Marx*, 2 vol. (1972–76), contains informative material on Marx's family life. Two good short biographies are ISAIAH BERLIN, *Karl Marx: His Life and Environment*, 4th ed. (1978, reprinted with corrections, 1982); and WERNER BLUMENBERG, *Portrait of Marx: An Illustrated Biography* (1972; originally published in German, 1962).

For introductory analysis and commentaries of Marx's works, see DAVID MCLELLAN, *The Thought of Karl Marx*, 2nd ed. (1980); BRUCE MAZLISH, *The Meaning of Karl Marx* (1984); W.A. SUCHTING, *Marx, an Introduction* (1983), and *Marx and Philosophy: Three Studies* (1986); and RICHARD SCHMITT, *Introduction to Marx and Engels: A Critical Reconstruction* (1987). TERRELL CARVER, *A Marx Dictionary* (1987), provides brief definitions of Marxian concepts without interpretative deviations from the original. For more detailed studies, see ROMAN ROSDOLSKY, *The Making of Marx's 'Capital'* (1977, reissued 1980; originally published in German, 1968); DEREK SAYER, *Marx's Method: Ideology, Science and Critique in Capital*, 2nd ed. (1983); ROBERT PAUL WOLFF, *Understanding Marx: A Reconstruction and Critique of Capital* (1984); HAL DRAPER, *Karl Marx's Theory of Revolution*, 3 vol. (1977–86); D. ROSS GANDY, *Marx and History: From Primitive Society to the Communist Future* (1979); MURRAY WOLFSON, *Marx: Economist, Philosopher, Jew: Steps in the Development of a Doctrine* (1982); DANIEL LITTLE, *The Scientific Marx* (1986); THOMAS SOWELL, *Marxism: Philosophy and Economics* (1985); and JOHN CUNNINGHAM WOOD (ed.), *Karl Marx's Economics: Critical Assessments*, 4 vol. (1987). A particularly acute summary of the difficulties in Marx's work is JON ELSTER, *Making Sense of Marx* (1985). Many monographs explore Marx's political and ideological development: CAROL C. GOULD, *Marx's Social Ontology: Individuality and Community in Marx's Theory of Social Reality* (1978, reprinted 1980), a study based on Marx's *Grundrisse*; RICHARD E. OLSEN, *Karl Marx* (1978); S.S. PRAWER, *Karl Marx and World Literature* (1976); PAUL THOMAS, *Karl Marx and the Anarchists* (1980); and ALLEN W. WOOD, *Karl Marx* (1981).

Marxism. Good introductions to the study of Marxism include LESZEK KOŁAKOWSKI, *Main Currents of Marxism: Its Rise, Growth, and Dissolution*, 3 vol. (1978, reprinted 1981; originally published in Polish, 1976–78); GEORGE LICHTHEIM, *Marxism: An Historical and Critical Study*, 2nd ed. (1964, reprinted 1982); and DAVID MCLELLAN, *Marxism After Marx* (1979, reissued 1981), which contains an extensive bibliography. Some important analyses are assembled in DAVID MCLELLAN (ed.), *Marxism: Essential Writings* (1988). Studies of Marxism as a sociological doctrine may be found in KARL KORSCH, *Karl Marx* (1938, reissued 1963); HENRI LEFEBVRE, *The Sociology of Marx* (1968, reprinted 1982; originally published in French, 1966);

and SIDNEY HOOK, *Towards the Understanding of Karl Marx* (1933). Developments in Marxism as a political theory are discussed in ALFRED SCHMIDT, *History and Structure: An Essay on Hegelian-Marxist and Structuralist Theories of History* (1981; originally published in German, 1971); DAVID RUBINSTEIN, *Marx and Wittgenstein: Social Praxis and Social Explanation* (1981); TOM ROCKMORE, *Fichte, Marx, and the German Philosophical Tradition* (1980); S.H. RIGBY, *Marxism and History: A Critical Introduction* (1987); and PAUL PHILLIPS, *Marx and Engels on Law and Laws* (1980). Specialized studies include STANLEY MOORE, *Marx on the Choice Between Socialism and Communism* (1980); JOSÉ PORFIRIO MIRANDA, *Marx Against the Marxists: The Christian Humanism of Karl Marx* (1980; originally published in Spanish, 1978); RALPH MILIBAND, *Marxism and Politics* (1977), including a discussion of the applicability of Marxism to contemporary politics in the Third World and communist countries; ROBERT L. HEILBRONER, *Marxism, For and Against* (1980); ANTHONY GIDDENS, *A Contemporary Critique of Historical Materialism*, 2 vol. (1981–85), an alternative, based on anthropological research, to the Marxist idea that all history has been the history of class struggle; MAURICE GODELIER, *Perspectives in Marxist Anthropology* (1977; originally published in French, 1973), presenting the contrasting view that classical Marxism may provide a methodology for analysis of empirical data in history and anthropology; and IAN CUMMINS, *Marx, Engels, and National Movements* (1980).

A. JAMES GREGOR, *A Survey of Marxism: Problems in Philosophy and the Theory of History* (1965), emphasizes philosophical problems in lieu of political or economic ones. The outstanding work on Marxist ethics is EUGENE KAMENKA, *The Ethical Foundations of Marxism*, 2nd ed. (1972). See also HUGO MEYNELL, *Freud, Marx, and Morals* (1981); and GARY NELSON and LAWRENCE GROSSBERG (eds.), *Marxism and Interpretation of Culture* (1988).

DAVID HOROWITZ (ed.), *Marx and Modern Economics* (1968), is an excellent collection of essays by leading economic theorists. Other treatments of Marxist economics worth consulting are PAUL M. SWEEZY, *The Theory of Capitalist Development: Principles of Marxian Political Economy* (1942, reissued 1970); and JOHN STRACHEY, *The Nature of Capitalist Crisis* (1935). The place of Marxist thought in the intellectual history of the 20th century is assessed in JACK LINDSAY, *The Crisis in Marxism* (1981); ANTHONY BREWER, *Marxist Theories of Imperialism: A Critical Survey* (1980); PERRY ANDERSON, *Considerations on Western Marxism* (1976); and WALTER L. ADAMSON, *Marx and the Disillusionment of Marxism* (1985).

An account of the historical development of Marxism can be found in HENRI CHAMBRE, *From Karl Marx to Mao Tse-Tung: A Systematic Survey of Marxism-Leninism* (1963; originally published in French, 1959). GEORGE D.H. COLE, *A History of Socialist Thought*, 5 vol. in 7 (1953–65), presents a detailed study of the Marxist movement rather than the ideas; see especially vol. 2, *Socialist Thought: Marxism and Anarchism, 1850–1890*. TOM BOTTOMORE (ed.), *Interpretations of Marx* (1988), is an authoritative collection of essays.

The development and influence of Russian, Soviet, and eastern European Marxist theories is covered in a number of works by both Marxist and non-Marxist authors: HERBERT MARCUSE, *Soviet Marxism: A Critical Analysis* (1958, reprinted 1985); BERTRAM D. WOLFE, *Revolution and Reality: Essays on the Origin and Fate of the Soviet System* (1981); BARUCH KNEI-PAZ, *The Social and Political Thought of Leon Trotsky* (1978); UMBERTO MELOTTI, *Marx and the Third World* (1977, reprinted 1982; originally published in Italian, 1971); ADAM WESTOBY, *Communism Since World War II* (1981); and ERNEST MANDEL, *Revolutionary Marxism Today* (1979). Specialized studies include DONALD C. HODGES, *The Bureaucratization of Socialism* (1981); ROBERT J. ALEXANDER, *The Right Opposition: The Lovestoneites and the International Communist Opposition of the 1930's* (1981); ESTHER KINGSTON-MANN, *Lenin and the Problem of Marxist Peasant Revolution* (1983); BOGDAN SZAJKOWSKI (ed.), *Marxist Governments: A World Survey*, 3 vol. (1981); V. KUBÁLKOVÁ and A.A. CRUICKSHANK, *Marxism-Leninism and Theory of International Relations* (1980); HORACE B. DAVIS, *Toward a Marxist Theory of Nationalism* (1978); ISAAC DEUTSCHER, *Marxism in Our Time* (1971); JOHN P. BURKE, LAWRENCE CROCKER, and LYMAN H. LEGTERS (eds.), *Marxism and the Good Society* (1981), on Russia and China; JOHN G. GURLEY, *Challengers to Capitalism: Marx, Lenin, Stalin, and Mao*, 3rd ed. (1988); and NICHOLAS ABERCROMBIE, STEPHEN HILL, and BRYAN S. TURNER, *The Dominant Ideology Thesis* (1980), a critique of current Marxist thought. Two important critical studies are DAVID LANE, *The Socialist Industrial State: Towards a Political Sociology of State Socialism* (1976); and DONALD WILHELM, *Creative Alternatives to Communism: Guidelines for Tomorrow's World* (1977, reprinted 1981).

Of special reference interest are JOHN LACHS, *Marxist Philosophy: A Bibliographical Guide* (1967); HARRY G. SHAFFER, *Periodicals on the Socialist Countries and on Marxism: A New Annotated Index of English-Language Publications* (1977); J. WILCZYNSKI, *An Encyclopedic Dictionary of Marxism, Socialism and Communism* (1981); and ROBERT A. GORMAN (ed.), *Biographical Dictionary of Marxism* (1986), and *Biographical Dictionary of Neo-Marxism* (1985), a compendium providing information on practitioners of Marxism in more than 50 countries. (D.T.McL.)

Masks

Simply defined, a mask is a form of disguise. It is an object that is frequently worn over or in front of the face to hide the identity of a person and by its own features to establish another being. This essential characteristic of hiding and revealing personalities or moods is common to all masks. As cultural objects they have been used throughout the world in all periods since the Stone Age and have been as varied in appearance as in their use and symbolism.

This article deals with the general characteristics, functions, and forms of masks. It is divided into the following sections:

GENERAL CHARACTERISTICS

Masks have been designed in innumerable varieties, from the simplest of crude "false faces" held by a handle to complete head coverings with ingenious movable parts and hidden faces. Mask makers have shown great resourcefulness in selecting and combining available materials. Among the substances utilized are woods, metals, shells, fibres, ivory, clay, horn, stone, feathers, leather, furs, paper, cloth, and corn husks. Surface treatments have ranged from rugged simplicity to intricate carving and from polished woods and mosaics to gaudy adornments.

Carl Frank

Mask worn with costume: *makishi* dancer, a masked ancestral spirit who assists at initiation rites of the tribes of the northwestern region of Zambia.

Masks generally are worn with a costume, often so complete that it entirely covers the body of the wearer. Fundamentally the costume completes the new identity represented by the mask, and usually tradition prescribes its appearance and construction to the same extent as the mask itself. Costumes, like the masks, are made of a great variety of materials, all of which have a symbolic connection with the mask's total imagery. Ideally the costume should be seen with the mask while the wearer is in action.

Anthropomorphic and theriomorphic masks

The morphological elements of the mask are with few exceptions derived from natural forms. Masks with human features are classified as anthropomorphic and those with animal characteristics as theriomorphic. In some instances, the mask form is a replication of natural features or closely follows the lineaments of reality, and in other instances it is an abstraction. Masks usually represent supernatural beings, ancestors, and fanciful or imagined figures and can also be portraits. The localization of a particular spirit in a specific mask must be considered a highly significant reason for its existence. The change in identity of the wearer for that of the mask is vital, for if the spirit represented does not reside in the image of the mask, the ritual petitions, supplications, and offerings made to it would be ineffectual and meaningless. The mask, therefore, most often functions as a means of contact with various spirit powers, thereby protecting against the unknown forces of the universe by prevailing upon their potential beneficence in all matters relative to life.

The making of masks. With few exceptions, masks have been made by professionals who were either expert in this particular craft or were noted sculptors or artisans. In societies in which masks of supernatural beings have played a significant ceremonial role, it is presumed that the spirit power of the created image usually is strongly felt by the artist. A primary belief involved in both the conception and the rendering of these objects was that spirit power dwelled in all organic and inorganic matter, and therefore the mask will contain the spirit power of whatever material was used to make it. This power is considered a volatile, active force that is surrounded by various taboos and restrictions for the protection of those handling it. Certain prescribed rituals frequently have to be followed in the process of the mask's creation. A spirit power is also often believed to inhabit the artist's tools so that even these have to be handled in a prescribed manner. As the form of the mask develops it is usually believed to acquire power increasingly in its own right, and again various procedures are prescribed to protect the craftsman and to ensure the potency of the object. If all the conventions have been adhered to, the completed mask, when worn or displayed, is regarded as an object suffused with great supernatural or spirit power. In some cultures it is believed that because of the close association between the mask maker and the spirit of the mask, the artist absorbs some of its magic power. A few West African tribal groups in Mali believe, in fact, that the creators of masks are even potentially capable of using the object's supernatural powers to cause harm to others.

Aesthetically, the mask maker has usually been restricted in the forms he can use since masks generally have a traditional imagery with formal conventions. If they are not followed, the artist can bring upon himself the severe censure of his social group and the displeasure or even wrath of the spirit power inherent in the mask. This requirement for accuracy, however, does not restrict artistic expressiveness. The mask maker can and does give his own creative interpretation to the traditionally prescribed general forms, attributes, and devices. The artist, in fact, is usually sought out as a maker of masks because of his

known ability to give a vitally expressive or an aesthetically pleasing presentation of the required image.

The wearing of masks. The wearer is also considered to be in direct association with the spirit force of the mask and is consequently exposed to like personal danger of being affected by it. For his protection, the wearer, like the mask maker, is required to follow certain sanctioned procedures in his use of the mask. In some respects he plays the role of an actor in cooperation or collaboration with the mask. Without his performing dance and posturing routines, which are often accompanied with certain sounds of music, the mask would remain a representation without a full life-force. The real drama and power of its form is the important contribution of the wearer. When he is attired in the mask, there is a loss of his previous identity and the assuming of a new one. Upon donning the mask, the wearer sometimes undergoes a psychic change and as in a trance assumes the spirit character depicted by the mask. Usually, however, the wearer skillfully becomes a "partner" of the character he is impersonating, giving to the mask not only an important spark of vitality by the light flashing from his own eyes but also bringing it alive by his movements and poses. But it would seem that the wearer often becomes psychologically completely attached to the character he is helping to create. He loses his own identity and becomes like an automaton, without his own will, which has become subservient to that of the personage of the mask. It appears, however, that at all times there remains some important, even if *sub rosa*, association between the mask and its wearer.

Supernatural and spirit powers

The role of the spectator. It is as consecrated objects imbued with supernatural power that masks are viewed by the spectators or participants at ceremonials where their presence is required. Whatever their specific identity may be, the masks usually refer back to early times, when their initial appearance occurred. This basic aspect of the mask is understood at least in essence by everyone. A paramount role of the mask is to give a sense of continuity between the present and the beginnings of time, a sense that is of vital importance for the integration of a culture with no written history. Psychologically the spectators become associated with the past through the spirit power of the mask, and this often leads the participants to a state of complete absorption or near-frenzy. This is not, however, a consistent reaction to masked ceremonials. That depends on the character whose presence the mask represents. In some cases, the spirit or supernatural being depicted is viewed with rejoicing and almost a familiarity, which leads to gaiety that has a cathartic aspect. Even so, the mask has a spirit content that is respected and revered, even if it is not showing a being with malignant potential. All of these forms have spirit and magical qualities and are thus esteemed as agents for the accomplishing of suprahuman acts.

Some masks, however, do represent malignant, evil, or potentially harmful spirits. These are often used to keep a required balance of power or a traditional social and political relationship of inherited positions within a culture. The characters depicted are also prescribed by tradition and enact roles to achieve the desired ends. The drama involving these masks is often associated with secret societies, especially in Africa, where the greatest range of mask forms and functions can be observed. These forms are often used in very restricted performances, where only select persons can view them. This is also true in other areas where masks are used, such as in Oceania, the Americas, and even in some of the folk mask rites still performed in Europe.

Meaning and aesthetic response. On the basis of present knowledge, it would appear that there is not or has not been any set response or reaction by any one of the three groups involved with the mask: the artist, the wearer, the spectator. There is, however, a reaction of a very particular kind common to every culture, a response such as awe, delight and pleasure, fear and even terror: these are as traditionally determined as the forms and costumes of the masks themselves. This is a learned and inherent pattern of conduct for each culture. Masks, therefore, that have a closely comparable appearance in several unrelated groups in quite different parts of the world often have totally dissimilar meanings and functions. It is thus practically impossible to determine either the meaning or use of a mask by its appearance alone. For example, some masks in Africa, as well as in Oceania and East Asia, have such a grotesque or frightening appearance as to lead one to suspect that they represent evil spirits with an intent to terrorize the spectators; actually they may have the opposite character and function. The significance of masks can be determined only by reference to accounts or personal observations of the masks in the setting of their own culture.

Art objects

The aesthetic effects of masks, on the other hand, since they derive from the forms and their disposition within the design, can readily be evaluated as art objects. But this evaluation is based on elements very different from those appraised within the mask's own culture. This is partly because the total artistic qualities of a mask derive both from its exterior forms and from its meaning and function within its cultural context. There exist, however, in all cultures criteria for determining the quality of objects as art. These criteria differ from one culture to another, and they may be known only from investigations carried out within the varying cultures.

Preservation and collecting. The preservation or disposal of masks is often decreed by tradition. Many masks and often their form and function are passed down through clans, families, special societies, or from individual to individual. They are usually spiritually reactivated or aesthetically restored by repainting and redecorating, without destroying the basic form and symbolism. In many instances, however, the mask is used only for one ceremony or occasion and then is discarded or destroyed, sometimes by burning.

The collecting of masks has largely been of recent origin. Not until the late 19th and early 20th century were they seriously appreciated as art objects or studied as cultural artifacts. Most masks have been obtained through archaeological excavations or in field expeditions, that is, in their place of origin.

THE FUNCTIONS AND FORMS OF MASKS

Masks are as extraordinarily varied in appearance as they are in function or fundamental meaning. Many masks are primarily associated with ceremonies that have religious and social significance or are concerned with funerary customs, fertility rites, or curing sickness. Other masks are used on festive occasions or to portray characters in a dramatic performance and in re-enactments of mythological events. Masks are also used for warfare and as protective devices in certain sports, as well as frequently being employed as architectural ornament.

Social and religious uses. Masks representing potentially harmful spirits were often used to keep a required balance of power or a traditional relationship of inherited positions within a culture. The forms of these masks invariably were prescribed by tradition, as were their uses. This type of mask was often associated with secret societies, especially in Africa, where the greatest range of types and functions can be found. They were also widely used among Oceanic peoples of the South Pacific and the American Indians and are even used in some of the folk rites still performed in Europe.

Admonitory and disciplinary masks

Masks have served an important role as a means of discipline and have been used to admonish women, children, and criminals. Common in China, Africa, Oceania, and North America, admonitory masks usually completely cover the features of the wearer. It is believed among some of the African Negro tribes that the first mask was an admonitory one. A child, repeatedly told not to, persisted in following its mother to fetch water. To frighten and discipline the child, the mother painted a hideous face on the bottom of her water gourd. Others say the mask was invented by a secret African society to escape recognition while punishing marauders. In New Britain, members of a secret terroristic society called the Dukduk appear in monstrous five-foot masks to police, to judge, and to execute offenders. Aggressive supernatural spirits of an almost demonic nature are represented by these masks, which are

Admonitory and ancestor masks.

constructed from a variety of materials, usually including tapa, or bark cloth, and the pith of certain reeds. These materials are painted in brilliant colours, with brick red and acid green predominating.

In many cultures throughout the world, a judge wears a mask to protect him from future recriminations. In this instance, the mask represents a traditionally sanctioned spirit from the past who assumes responsibility for the decision levied on the culprit.

Ancestor masks

Rituals, often nocturnal, by members of secret societies wearing ancestor masks are reminders of the ancient sanction of their conduct. In many cultures, these masked ceremonials are intended to prevent miscreant acts and to maintain the circumscribed activities of the tribe. Along the Guinea coast of West Africa, for instance, many highly realistic masks represent ancestors who enjoyed specific cultural roles; the masks symbolize sanction and control when donned by the wearer. Among some of the Dan and Ngere tribes of Liberia and Ivory Coast, ancestor masks with generic features act as intermediaries for the transmission of petitions or offerings of respect to the gods. These traditional ancestral emissaries exert by their spirit power a social control for the community.

Particularly among Oceanic peoples, American Indians, and Negro tribes of Africa, certain times of the year are set aside to honour spirits or ancestors. Among nonliterate peoples who cannot record their own histories, masked rituals act as an important link between past and present, giving a sense of historic continuity that strengthens their social bond. On these occasions, masks usually recognizable as dead chieftains, relatives, friends, or even foes are worn or exhibited. Gifts are made to the spirits incarnated in the masks, while in other instances dancers wearing stylized mourning masks perform the prescribed ceremony.

In western Melanesia, the ancestral ceremonial mask occurs in a great variety of forms and materials. The Sepik River area in north central New Guinea is the source of an extremely rich array of these mask forms mostly carved in wood, ranging from small faces to large fantastic forms with a variety of appendages affixed to the wood, including shell, fibre, animal skins, seed, flowers, and feathers. These masks are highly polychromed with earth colours of red and yellow, lime white, and charcoal black. They often represent supernatural spirits as well as ancestors and therefore have both a religious and a social significance.

Initiation masks

Members of secret societies usually conduct the rituals of initiation, when a young man is instructed in his future role as an adult and is acquainted with the rules controlling the social stability of the tribe. Totem and spiritualistic masks are donned by the elders at these ceremonies. Sometimes the masks used are reserved only for initiations. Among the most impressive of the initiation masks are the exquisitely carved human faces of west coast African Negro tribes. In western and central Zaire, in Africa, large, colourful helmetlike masks are used as a masquerading device when the youth emerges from the initiation area and is introduced to the villagers as an adult of the tribe. After a lengthy ordeal of teaching and initiation rites, for instance, a youth of the Pende tribe appears in a distinctive colourful mask indicative of his new role as an adult. The mask is later cast aside and replaced by a

small ivory duplicate, worn as a charm against misfortune and as a symbol of his manhood.

Totem masks

Believing everything in nature to possess a spirit, man found authority for himself and his family by identifying with a specific nonhuman spirit. He adopted an object of nature; then he mythologically traced his ancestry back to the chosen object; he preempted the animal as the emblem of himself and his clan. This is the practice of totem, which consolidates family pride and distinguishes social lines. Masks are made to house the totem spirit. The totem ancestor is believed actually to materialize in its mask; thus masks are of the utmost importance in securing protection and bringing comfort to the totem clan.

The Papuans of New Guinea build mammoth masks called *hevehe,* attaining 20 feet in height. They are constructed of a palm wood armature covered in bark cloth; geometric designs are stitched on with painted cane strips. These fantastic man–animal masks are given a frightening aspect. When they emerge from the men's secret clubhouse, they serve to protect the members of the clan. The so-called "totem" pole of the Alaskan and British Columbian Indian fulfills the same function. The African totem mask is often carved from ebony or other hard woods, designed with graceful lines and showing a highly polished surface. Animal masks, their features elongated and beautifully formalized, are common in western Africa. Dried grass, woven palm fibres, coconuts, and shells, as well as wood are employed in the masks of New Guinea, New Ireland, and New Caledonia. Represented are fanciful birds, fishes, and animals with distorted or exaggerated features.

The high priest and medicine man, or the shaman, frequently had his own very powerful totem, in whose mask he could exorcise evil spirits, punish enemies, locate game or fish, predict the weather, and, most importantly, cure disease.

The Northwest Coast Indians of North America in particular devised mechanical masks with movable parts to reveal a second face—generally a human image. Believing that the human spirit could take animal form and vice versa, the makers of these masks fused man and bird or man and animal into one mask. Some of these articulating masks acted out entire legends as their parts moved.

Funerary and commemorative uses. In cultures in which burial customs are important, anthropomorphic masks have often been used in ceremonies associated with the dead and departing spirits. Funerary masks were frequently used to cover the face of the deceased. Generally their purpose was to represent the features of the deceased, both to honour them and to establish a relationship through the mask with the spirit world. Sometimes they were used to force the spirit of the newly dead to depart for the spirit world. Masks were also made to protect the deceased by frightening away malevolent spirits.

Burial masks

From the Middle Kingdom (*c.* 2040–1786 BC) to the 1st century AD, the ancient Egyptians placed stylized masks with generalized features on the faces of their dead. The funerary mask served to guide the spirit of the deceased back to its final resting place in the body. They were commonly made of cloth covered with stucco or plaster, which was then painted. For more important personages, silver and gold were used. Among the most splendid examples of the burial portrait mask is the one created *c.* 1350 BC for the pharaoh Tutankhamen. In Mycenaean tombs of

Use by the Incas

c. 1400 BC, beaten gold portrait masks were found. Gold masks also were placed on the faces of the dead kings of Cambodia and Siam.

The mummies of Inca royalty wore golden masks. The mummies of lesser personages often had masks that were made of wood or clay. Some of these ancient Andean masks had movable parts, such as the metallic death mask with movable ears that was found in the Moon Pyramid at Moche, Peru. The ancient Mexicans made burial masks that seem to be generic representations rather than portraits of individuals.

In ancient Roman burials, a mask resembling the deceased was often placed over his face or was worn by an actor hired to accompany the funerary cortege to the burial site. In patrician families these masks or *imagines* were sometimes preserved as ancestor portraits and were displayed on ceremonial occasions. Such masks were usually modelled over the features of the dead and cast in wax. This technique was revived in the making of effigy masks for the royalty and nobility of Europe from the late Middle Ages through the 18th century. Painted and with human hair, these masks were attached to a dummy dressed in state regalia and were used for display, processionals, or commemorative ceremonials. From the 17th century to the 20th, death masks of famous persons became widespread among European peoples. With wax or liquid plaster of paris, a negative cast of the human face could be produced that in turn acted as a mold for the positive image, frequently cast in bronze. In the 19th century, life masks made in the same manner became popular. Another type of life mask had been produced in the Fayyum region of Egypt during the 1st and 2nd centuries AD. These were realistic portraits painted in encaustic on wood during a person's lifetime; when the person died, they were attached directly to the facial area on the mummy shroud.

Death and life masks

The skull mask is another form usually associated with funerary rites. The skull masks of the Aztecs, like their wooden masks, were inlaid with mosaics of turquoise and lignite, and the eye sockets were filled with pyrites.

(Right) False Face Society mask of the Iroquois Indians of North America.

Holes were customarily drilled in the back so the mask might be hung or possibly worn. In Melanesia, the skull of the deceased is often modelled over with clay, or resin and wax, and then elaborately painted with designs that had been used ceremonially by the deceased during his own lifetime.

Therapeutic uses. Masks have played an important part in magico-religious rites to prevent and to cure disease. In some cultures, the masked members of secret societies could drive disease demons from entire villages and tribes. Among the best known of these groups was the False Face Society of the North American Iroquois Indians. These professional healers performed violent pantomimes to exorcise the dreaded *Gahadogoka gogosa* (demons who plagued the Iroquois). They wore grimacing, twisted masks, often with long wigs of horsehair. Metallic inserts often were used around the eyes to catch the light of the campfire and the moon, emphasizing the grotesqueness of the mask.

Masks for protection from disease include the measle masks worn by Chinese children and the cholera masks worn during epidemics by the Chinese and Burmese. The disease mask is most developed among the Sinhalese in Sri Lanka (Ceylon), where 19 distinct *rākasa*, or disease devil masks, have been devised. These masks are of ferocious aspect, fanged, and with startling eyes. Gaudily coloured and sometimes having articulating jaws, they present a dragon-like appearance.

Uses in warfare and sport

Masks have long been used in military connections. A war mask will have a malevolent expression or hideously fantastic features to instill fear in the enemy. The ancient Greeks and Romans used battle shields with grotesque masks or attached terrifying masks to their armour, as did the Chinese warrior. Grimacing *menpo*, or mask helmets, were used by Japanese samurai.

Many sports require the use of masks. Some of these are merely functional, protective devices such as the masks worn by fencers, baseball catchers, or even skiers. To protect their faces in sports events and tournaments of arms, horsemen of the Roman army attached highly decorative and symbolic masks to their helmets.

Perhaps the earliest use of masks was in connection with hunting. Disguise masks were seemingly used in the early Stone Age in stalking prey and later to house the slain animal's spirit in the hope of placating it. The traditional animal masks worn by the Altaic and Tungusic shamans in Siberia are strictly close to such prehistoric examples as the image of the so-called sorcerer in the Cave of Les Trois Frères in Ariège, France.

Uses in fertility ceremonies

Since agricultural societies first appeared in prehistory, the mask has been widely used for fertility rituals. The Iroquois, for instance, used corn husk masks at harvest rituals to give thanks for and to achieve future abundance of crops. Perhaps the most renowned of the masked fertility rites held by American Indians are those still performed by the Hopi and Zuni Indians of the Southwest U.S. Together with masked dancers representing clouds, rain spirits, stars, Earth Mother, sky god, and others, the shaman takes part in elaborate ceremonies designed to assure crop fertility. Spirits called *kachinas*, who first brought rain to the Pueblo tribes, are said to have left their masks behind when sent to dwell in the bottom of a desert lake. Their return to help bring the rain is incarnated by the masked dancer. Cylindrical masks, covering the entire head and resting on the shoulders, are of a primal type. They are made of leather and humanized by the addition of hair and a variety of adjuncts. Eyes are represented by incisions or by buckskin balls filled with deer hair and affixed to the mask. The nose is often of rolled buckskin or corncob. Frequently the mask has a projecting wooden cylinder for a bill or a gourd stem cut with teeth for a snout. Horns are attached to some masks. Many colours are used in their painting; plumes and beads are attached, and the sex of the mask is distinguished by its shape: round head indicates male and square indicates female. In the western Sudan area of Africa many tribes have masked fertility ceremonials. The *segoni-kun* masks that are fashioned by the Bambara tribes in Mali are aesthetically among the most interesting. Antelopes, characterized by their elegant simplicity, are carved in wood and affixed to woven fibre caps that are hung with raffia and cover the wearer. The antelope is believed to have introduced agriculture, and so when crops are sown, members of Tjiwara society cavort in the fields in pairs to symbolize fertility and abundance.

Festive uses. Masks for festive occasions are still commonly used in the 20th century. Ludicrous, grotesque, or superficially horrible, festival masks are usually conducive to good-natured license, release from inhibitions, and ribaldry. These include the Halloween, Mardi Gras, or "masked ball" variety. The disguise is assumed to create a momentary, amusing character, often resulting in humorous confusions, or to achieve anonymity for the prankster or ribald reveller.

Throughout contemporary Europe and Latin America, masks are associated with folk festivals, especially those generated by seasonal changes or marking the beginning and end of the year. Among the most famous of the folk masks are the masks worn to symbolize the driving away of winter in parts of Austria and Switzerland. In Mexico and Guatemala, annual folk festivals employ masks for storytelling and caricature, such as for the Dance of the Old Men and the Dance of the Moors and the Christians. The Eskimo make masks with comic or satiric features

that are worn at festivals of merrymaking, as do the Ibos of Nigeria.

Theatrical uses. Masks have been used almost universally to represent characters in theatrical performances. Theatrical performances are a visual literature of a transient, momentary kind. It is most impressive because it can be seen as a reality; it expends itself by its very revelation. The mask participates as a more enduring element, since its form is physical.

Ancient Greek and Roman

The mask as a device for theatre first emerged in Western civilization from the religious practices of ancient Greece. In the worship of Dionysus, god of fecundity and the harvest, the communicants' attempt to impersonate the deity by donning goatskins and by imbibing wine eventually developed into the sophistication of masking. When a literature of worship appeared, a disguise, which consisted of a white linen mask hung over the face (a device supposedly initiated by Thespis, a 6th-century-BC poet who is credited with originating tragedy), enabled the leaders of the ceremony to make the god manifest. Thus symbolically identified, the communicant was inspired to speak in the first person, thereby giving birth to the art of drama. In Greece the progress from ritual to ritual-drama was continued in highly formalized theatrical representations. Masks used in these productions became elaborate headpieces made of leather or painted canvas and depicted an extensive variety of personalities, ages, ranks, and occupations. Heavily coiffured and of a size to enlarge the actor's presence, the Greek mask seems to have been designed to throw the voice by means of a built-in megaphone device and, by exaggeration of the features, to make clear at a distance the precise nature of the character. Moreover, their use made it possible for the Greek actors—who were limited by convention to three speakers for each tragedy—to impersonate a number of different characters during the play simply by changing masks and costumes. Details from frescoes, mosaics, vase paintings, and fragments of stone sculpture that have survived to the present day provide most of what is known of the appearance of these ancient theatrical masks. The tendency of the early Greek and Roman artists to idealize their subjects throws doubt, however, upon the accuracy of these reproductions. In fact, some authorities maintain that the masks of the ancient theatre were crude affairs with little aesthetic appeal.

Medieval and Renaissance

In the Middle Ages, masks were used in the mystery plays of the 12th to the 16th century. In plays dramatizing portions of the Old and New Testaments, grotesques of all sorts, such as devils, demons, dragons, and personifications of the seven deadly sins, were brought to stage life by the use of masks. Constructed of papier-mâché, the masks of the mystery plays were evidently marvels of ingenuity and craftsmanship, being made to articulate and to belch fire and smoke from hidden contrivances. But again, no reliable pictorial record has survived. Masks used in connection with present-day carnivals and Mardi Gras and those of folk demons and characters still used by central European peasants, such as the *Perchten* masks of Alpine Austria, are most likely the inheritors of the tradition of medieval masks.

The 15th-century Renaissance in Italy witnessed the rise of a theatrical phenomenon that spread rapidly to France, to Germany, and to England, where it maintained its popularity into the 18th century. Comedies improvised from scenarios based upon the domestic dramas of the ancient Roman comic playwrights Plautus (254?–184 BC) and Terence (186/185–159 BC) and upon situations drawn from anonymous ancient Roman mimes flourished under the title of commedia dell'arte. Adopting the Roman stock figures and situations to their own usages, the players of the commedia were usually masked. Sometimes the masking was grotesque and fanciful, but generally a heavy leather mask, full or half face, disguised the commedia player. Excellent pictorial records of both commedia costumes and masks exist; some sketches show the characters of Arlecchino and Colombina wearing black masks covering merely the eyes, from which the later masquerade mask is certainly a development.

Modern

Except for vestiges of the commedia in the form of puppet and marionette shows, the drama of masks all but disappeared in Western theatre during the 18th, 19th, and first half of the 20th centuries. In modern revivals of ancient Greek plays, masks have occasionally been employed, and such highly symbolic plays as *Die versunkene Glocke* (*The Sunken Bell*; 1897) by the German Gerhart Hauptmann (1862–1946) and dramatizations of *Alice in Wonderland* have required masks for the performers of grotesque or animal figures. The Irish poet-playwright W.B. Yeats (1865–1939) revived the convention in his *Dreaming of the Bones* and in other plays patterned upon the Japanese Nō drama. In 1926 theatregoers in the United States witnessed a memorable use of masks in *The Great God Brown* by the American dramatist Eugene O'Neill (1888–1953), wherein actors wore masks of their own faces to indicate changes in the internal and external lives of their characters. Oskar Schlemmer (1888–1943), a German artist associated with the Bauhaus, became interested in the late 1920s and '30s in semantic phenomenology as applied to the design of masks for theatrical productions. Modern art movements are often reflected in the design of contemporary theatrical masks. The stylistic concepts of Cubism and Surrealism, for example, are apparent in the masks executed for a 1957 production of *La favola*

del figlio cambiato (*The Fable of the Transformed Son*) by the Italian dramatist Luigi Pirandello (1867–1936). A well-known mid-century play using masks was *Les Nègres* (1958; *The Blacks,* 1960) by the French writer Jean Genet. The mask, however, has unquestionably lost its importance as a theatrical convention in the 20th century, and its appearance in modern plays is unusual.

East Asian

In many ways akin to Greek drama in origin and theme, the Nō drama of Japan has remained a significant part of national life since its beginnings in the 14th century. Nō masks, of which there are about 125 named varieties, are rigidly traditional and are classified into five general types: old persons (male and female), gods, goddesses, devils, and goblins. The material of the Nō mask is wood with a coating of plaster, which is lacquered and gilded. Colours are traditional. White is used to characterize a corrupt ruler; red signifies a righteous man; a black mask is worn by the villain, who epitomizes violence and brutality. Nō masks are highly stylized and generally characterized. They are exquisitely carved by highly respected artists known as *tenka-ichi,* "the first under heaven." Shades of feeling are portrayed with beautifully sublimated realism. When the masks are subtly moved by the player's hand or body motion, their expression appears to change.

In Tibet, sacred dramas are performed by masked lay actors. A play for exorcising demons called the "Dance of the Red Tiger Devil" is performed at fixed seasons of the year exclusively by the priests or lamas wearing awe-inspiring masks of deities and demons. Masks employed in this mystery play are made of papier-mâché, cloth, and occasionally gilt copper. In the Indian state of Sikkim and in Bhutan, where wood is abundant and the damp climate is destructive to paper, they are carved of durable wood. All masks of the Himalayan peoples are fantastically painted and are usually provided with wigs of yak tail in various colours. Formally they often emphasize the hideous.

Masks, usually made of papier-mâché, are employed in the religious or admonitory drama of China; but for the greater part the actors in popular or secular drama make up their faces with cosmetics and paint to resemble masks, as do the Kabuki actors in Japan. The makeup mask both identifies the particular character and conveys his personality. The highly didactic sacred drama of China is performed with the actors wearing fanciful and grotesque masks. Akin to this "morality" drama are the congratulatory playlets, pageants, processions, and dances of China. Masks employed in these ceremonies are highly ornamented, with jewelled and elaborately filigreed headgears. In the lion and dragon dances of both China and Japan, a stylized mask of the beast is carried on a pole by itinerant players, whose bodies are concealed by a dependent cloth. The mask and cloth are manipulated violently, as if the animal were in pursuit, to the taps of a small drum. The mask's lower jaw is movable and made to emit a loud continuous clacking by means of a string.

Indonesian

On Java and Bali, wooden masks, *tupeng,* are used in certain theatrical performances called *wayang wong.* These dance dramas developed from the shadow puppet plays of the 18th century and are performed not only as amusement but as a safeguard against calamities. The stories are in part derived from ancient Sanskrit literature, especially the Hindu epics, although the Javanese later became Muslims. The brightly painted masks are made of wood and leather and are often fitted with horsehair and metallic or gilded paper accoutrements. They are ordinarily held in the teeth by means of a strap of leather or rattan that has been fastened across the inside. Occasionally an actor interrupts the unseen narrator, the Dalang, who is speaking the play. The mask is then held in front of the face while the player says his line. The use of theatrical masks in Java is exceptional, since masks, being forbidden under the prohibition of images, are practically unknown in the Islāmic world.

In the 20th century, with the breaking down of primitive and folk cultures, the mask has increasingly become a decorative object, although it has long been used in art as an ornamental device. In Haiti, India, Indonesia, Japan, Kenya, and Mexico, masks are produced largely for tourists. The collecting of old masks has been a part of the current interest in so-called primitive and folk arts. Masks also have exerted a decided influence on modern art movements, especially in the first decades of the 20th century, when painters in France and Germany found a source of inspiration in the tribal masks of Africa and western Oceania.

Materials Science

Materials science is the study of the properties of solid materials and how those properties are determined by a material's composition and structure. It grew out of an amalgam of solid-state physics, metallurgy, and chemistry, since the rich variety of materials properties cannot be understood within the context of any single classical discipline. With a basic understanding of the origins of properties, materials can be selected or designed for an enormous variety of applications, ranging from structural steels to computer microchips. Materials science is therefore important to many engineering activities such as electronics, aerospace, telecommunications, information processing, nuclear power, and energy conversion.

This article approaches the subject of materials science through five major fields of application: energy, ground transportation, aerospace, computers and communications, and medicine. The discussions focus on the fundamental requirements of each field of application and on the abilities of various materials to meet those requirements.

The many materials studied and applied in materials science are usually divided into four categories: metals, polymers, semiconductors, and ceramics. The sources, processing, and fabrication of these materials are explained at length in three *Macropædia* articles: INDUSTRIES, EXTRACTION AND PROCESSING; INDUSTRIES, CHEMICAL PROCESS; and INDUSTRIAL GLASS AND CERAMICS. Atomic and molecular structures are discussed in CHEMICAL ELEMENTS and MATTER. The applications covered in this article are given broad coverage in ENERGY CONVERSION, TRANSPORTATION, ELECTRONICS, and MEDICINE.

For coverage of related topics in the *Macropædia* and *Micropædia*, see the *Propædia*, sections 10/37, 111, 121, 125, 126, 334, 336, 712, 721, 724, 725, 734, and 735, and the *Index*.

This article is divided into the following sections:

Materials for energy

An industrially advanced society uses energy and materials in large amounts. Transportation, heating and cooling, industrial processes, communications—in fact, all the physical characteristics of modern life—depend on the flow and transformation of energy and materials through the techno-economic system. These two flows are inseparably intertwined and form the lifeblood of industrial society. The relationship of materials science to energy usage is pervasive and complex. At every stage of energy production, distribution, conversion, and utilization, materials play an essential role, and often special materials properties are needed. Remarkable growth in the understanding of the properties and structures of materials enables new materials, as well as improvements of old ones, to be developed on a scientific basis, thereby contributing to greater efficiency and lower costs.

CLASSIFICATION OF ENERGY-RELATED MATERIALS

Passive and active materials

Energy materials can be classified in a variety of ways. For example, they can be divided into materials that are passive or active. Those in the passive group do not take part in the actual energy-conversion process but act as containers, tools, or structures such as reactor vessels, pipelines, turbine blades, or oil drills. Active materials are those that take part directly in energy conversion—such as solar cells, batteries, catalysts, and superconducting magnets.

Another way of classifying energy materials is by their use in conventional, advanced, and possible future energy systems. In conventional energy systems such as fossil fuels, hydroelectric generation, and nuclear reactors, the materials problems are well understood and are usually associated with structural mechanical properties or long-standing chemical effects such as corrosion. Advanced energy systems are in the development stage and are in actual use in limited markets. These include oil from shale and tar sands, coal gasification and liquefaction, photovoltaics, geothermal energy, and wind power. Possible future energy systems are not yet commercially deployed to any significant extent and require much more research before they can be used. These include hydrogen fuel and fast-breeder reactors, biomass conversion, and superconducting magnets for storing electricity.

Classifying energy materials as passive or active or in relation to conventional, advanced, or future energy systems is useful because it provides a picture of the nature and degree of urgency of the associated materials requirements. But the most illuminating framework for understanding the relation of energy to materials is in the materials properties that are essential for various energy applications. Because of its breadth and variety, such a framework is best shown by examples. Accordingly, some of the most important materials properties that are needed for specific energy applications are listed in Table 1. The table could be greatly enlarged, but it is sufficient to show that inexpensive and abundant energy depends on the availability of materials with special properties. Each entry in the table states a critical property for the given application. For each application, many materials properties are utilized, but the table lists only those that are obviously most important. In oil refining, for example, reaction vessels must have certain mechanical and thermal properties, but catalysis is the critical process.

APPLICATIONS OF ENERGY-RELATED MATERIALS

High-temperature materials. In order to extract useful work from a fuel, it must first be burned so as to bring some fluid (usually steam) to high temperatures. Thermodynamics indicates that the higher the temperature, the greater the efficiency of the conversion of heat to work; therefore, the development of materials for combustion chambers, pistons, valves, rotors, and turbine blades that can function at ever-higher temperatures is of critical importance. The first steam engines had an efficiency of less than 1 percent, while modern steam turbines achieve efficiencies of 35 percent or more. Part of this improvement has come from improved design and metalworking accuracy, but a large portion is the result of using improved high-temperature materials. The early engines

Table 1: Materials Properties for Energy Applications

application	materials properties					
	mechanical	thermal	chemical	electric	magnetic	optical
Heat engine	high-temperature strength		corrosion resistance			
Oil-well drill bits	hardness					
Oil refining			catalysis			
Electricity generator	wear resistance and high-temperature strength			insulation	electromagnetism	
Nuclear fuel	swelling control					
Nuclear steam generator	resistance to stress corrosion and cracking		corrosion resistance			
Nuclear pressure vessel	resistance to crack growth					
Nuclear waste disposal			encapsulation; barriers			
Coal liquefaction and gasification	erosion resistance		catalysis			
Fuel cell			catalysis; corrosion resistance	electrolysis		
Solar energy		heat absorption		photoelectricity		reflectance
Wind power	fatigue resistance					
Geothermal energy			corrosion resistance			
Batteries				high energy density		
Superconductor	ductility; strength			high current capacity	magnetic quenching	
Hydrogen fuel			hydrogen absorption capacity	electrolysis		
Conservation	light weight; strength	thermal insulation; high-temperature resistance	low-temperature catalysis	semiconductivity	magnetic efficiency	low transmission loss

were made of cast iron and then ordinary steels. Later, high-temperature alloys containing nickel, molybdenum, chromium, and silicon were developed that did not melt or fail at temperatures above 540° C (1,000° F). But modern combustion processes are nearing the useful temperature limits that can be achieved with metals, and so new materials that can function at higher temperatures—particularly intermetallic compounds and ceramics—are being developed.

The problem of dislocations in metals

The structural features that limit the use of metals at high temperatures are both atomic and electronic. All materials contain dislocations. The simplest of these are the result of planes of atoms that do not extend all through the crystal, so that there is a line where the plane ends that has fewer atoms than normal. In metals, the outer electrons are free to move. This gives a delocalized cohesion so that, when a stress is applied, dislocations can move to relieve the stress. The result is that metals are ductile: not only can they be easily worked into desired shapes, but when stressed they will gradually yield plastically rather than breaking immediately. This is a desirable feature, but the higher the temperature, the greater the plastic flow under stress—and, if the temperature is too high, the material will become useless. In order to get around this, materials are being studied in which the motion of dislocations is inhibited. Ceramics such as silicon nitride or silicon carbide and intermetallics such as nickel aluminide hold promise because the electrons that hold them together are highly localized in the form of valence or ionic bonds. It is as if metals were held together by a slippery glue while in nonmetals the atoms were connected by rigid rods. Dislocations thus find it much harder to move in nonmetals; raising the temperature does not increase dislocation motion, and the stress needed to make them yield is much higher. Furthermore, their melting points are significantly higher than those of metals, and they are much more resistant to chemical attack. But these desirable features come at a price. The very structure that makes them attractive also makes them brittle; that is, they do not flow when subject to a high stress and are prone to failure by cracking. Modern research is aimed at overcoming this lack of ductility by modification of the material and how it is made. Hot pressing of ceramic powders, for example, minimizes the number of defects at which cracks can start, and the addition of small amounts of certain metals to intermetallics strengthens the cohesion among crystal grains at which fractures normally develop. Such advances, along with intelligent design, hold the promise of being able to build heat engines of much higher efficiency than those now available.

Diamond drills. Diamond drill bits are an excellent example of how an old material can be improved. Diamond is the hardest known substance and would make an excellent drill bit except that it is expensive and has weak planes in its crystal structure. Because natural diamonds are single crystals, the planes extend throughout the material, and they cleave easily. Such cleavage planes allow a diamond cutter to produce beautiful gems, but they are a disaster for drilling through rock. This limitation was overcome by Stratapax, a sintered diamond material developed by the General Electric Company of the United States. This consists of synthetic diamond powder that is formed into a thin plate and bonded to tungsten-carbide studs by sintering (fusing by heating the material below the melting point). Because the diamond plate is polycrystalline, cleavage cannot propagate through the material. The result is a very hard bit that does not fail by cleavage when it is used to drill through rock to get at oil and natural gas.

Oil platforms. An important example of dealing with old problems by modern methods is provided by the prevention of crack growth in offshore oil-drilling platforms. The primary structure consists of welded steel tubing that is subject to continually varying stress from ocean waves. Since the cost of building and deploying a platform can amount to several billion dollars, it is imperative that the platform have a long life and not be lost because of premature metal failure.

The growth of cracks

In the North Sea, 75 percent of the waves are higher than two metres (six feet) and exert considerable stresses on the platform. Cyclic loading of a metal ultimately results in fatigue failure in which surface cracks form, grow over time, and eventually cause the metal to break. Welds are the weak spots for such a process because weld metal has mechanical properties that are inferior to steel, and these are made even worse by internal stresses and defects (such as tiny voids and oxide particles) that are introduced in the welding process. Furthermore, the tube geometry at the weld consists of T- and K-shaped joints, which are natural stress concentrators. Fatigue failure in oil platforms therefore takes place at welds.

Fatigue occurs because cyclic stress causes dislocations to form and to move back and forth in the metal. Dislocation motion can be impeded by the presence of barriers such as small voids, grain boundaries, other dislocations, impurities, or even the surface itself. When dislocations are thereby pinned down, they stop the motion of other dislocations created by the stress, and a tangled dislocation network forms that results in a hard spot in the weld. The stress is then not easily relieved, and types of dislocation motion that are characteristic of the fatigue process initiate a crack at the weld surface. This phenomenon is a direct result of the microstructure of the weld and could be minimized by making the weld very uniform, preferably of the same material as the tubing, and having a very gently curved geometry at the joint. But, in spite of the sophistication of modern welding techniques, this is not yet feasible. An alternate strategy is therefore used in which the progress of the weld crack is monitored so that repairs can be made in time to avoid catastrophic failure. This can be done because, given the geometry of the joint, the depth of the crack is proportional to time until the crack is quite large. By contrast, in laboratory tests in which simple strips of metal are subject to cyclic stress, the growth rate increases as the crack becomes larger. In the T or K configuration in oil platforms, stress is much more evenly distributed, and the crack does not grow at an increasing speed until it is close to being fatal.

A technique for measuring the crack depth is based on the skin effect, the phenomenon in which a high-frequency alternating current is confined to the surface of a conductor. This makes it possible to measure the surface area of a small region with a simple meter, since an increase in crack depth means an increase in current path, and this in turn causes an increase in voltage drop. Measurement over time then allows the time to failure to be estimated; repairs can be effected before failure occurs. In this case, a knowledge of microstructure, the materials science of fatigue, and the study of crack formation have led to a simple testing technique of great economic importance.

Mathematical modeling of mass motion and heat transfer (including convection), along with studies of solidification, gas dissolution, and the effects of fluxes, are providing a much more detailed understanding of the factors controlling weld structure. With this knowledge, it should be possible to make welds with far fewer defects.

Radioactive waste. A different example is provided by the disposal of radioactive waste. Here the issue is primarily safety and the perception of safety rather than economics. Waste disposal will continue to be one of the factors that inhibit the exploitation of nuclear power until the public perceives it as posing no danger. The current plan is to interpose three barriers between the waste and human beings by first encapsulating it in a solid material, putting that in a metal container, and finally burying that container in geologically stable formations. The first step requires an inert, stable material that will hold the radioactive atoms trapped for a very long time, while the second step requires a material that is highly resistant to corrosion and degradation.

Encapsulation

There are two good candidates for encapsulation. The first is borosilicate glass; this can be melted with the radioactive material, which then becomes a part of the glass structure. Glass has a very low solubility, and atoms in it have a very low rate of migration, so that it provides an excellent barrier to the escape of radioactivity. However, glass devitrifies at the high temperatures resulting from the heat of radioactive decay; that is to say, the amorphous glassy state becomes crystalline, and, during this process, many cracks form in the material so that it no longer provides a good barrier against the escape of radioactive atoms. (This problem is more severe in rock than in salt formations, because salt has higher thermal conductivity than rock and dissipates the heat more easily.) The problem can be eased by storing the waste above ground for a decade or so. This would allow the initially high rate of decay to decrease, thereby lowering the temperature that would be reached after encapsulation. Handled in this way, borosilicate glass would be an excellent encapsulation material for reactor waste that had been aged for a decade or so.

The other candidate is a synthetic rock made of mineral mixtures such as zirconolite and perovskite. These are very insoluble and, in their natural state, are known to have sequestered radioactive elements for hundreds of millions of years. They are crystalline, ceramic materials whose crystal structures allow radioactive atoms to be immobilized within them. They are not subject to devitrification, since they are already crystalline.

Once encapsulated, radioactive waste must be put into canisters that are corrosion-resistant. These can be made of nickel-steel alloys, but the best candidate so far is a titanium material containing small amounts of nickel and molybdenum and traces of carbon and iron. Even though they are meant to be buried in as dry an environment as possible, these metals are tested by immersing them in brine. Tests show that seawater at 250° C (480° F) would corrode away less than one micrometre (one-thousandth of a millimetre, or four ten-thousandths of an inch) of the surface of the titanium material (known as Ti code 12) per year. This remarkable performance is primarily the result of a tough, highly resistant oxide skin that forms on titanium when exposed to oxygen. It would take thousands of years for the canisters to be penetrated by corrosion.

In order to estimate the effectiveness of such waste disposal, it must be noted that the waste is highly radioactive and dangerous initially but that the danger decreases with time. Radioactivity decays to such levels that the danger is much less after a few hundred years, extremely low after 500 years, and negligible after 1,000 years. In order to breach the triple-barrier system, groundwater must migrate to the canister, eat it away, and then leach out the radioactive atoms from the encapsulating glass or ceramic. This is a process that most probably would take far longer than a single millennium. A careful application of materials science can make radioactive waste disposal safer than current disposal methods for other toxic wastes.

Radioactive decay

Photovoltaics. Photovoltaic systems are an attractive alternative to fossil or nuclear fuels for the generation of electricity. Sunlight is free, it does not use up an irreplaceable resource, and its conversion to electricity is nonpolluting. In fact, photovoltaics are now in use where power lines from utility grids are either not possible or do not exist, as in outer space or remote, nonurban locations.

The barrier to widespread use of sunlight to generate electricity is the cost of photovoltaic systems. The application of materials science is essential in efforts to lower the cost to levels that can compete with those for fossil or nuclear fuels.

The conversion of light to electricity depends on the electronic structure of solar cells with two or more layers of semiconductor material that can absorb photons, the primary energy packets of light. The photons raise the energy level of the electrons in the semiconductor, exciting some to jump from the lower-energy valence band to the higher-energy conduction band. The electrons in the conduction band and the holes they have left behind in the valence band are both mobile and can be induced to move by a voltage. The electron motion, and the movement of holes in the opposite direction, constitute an electric current. The force that drives electrons and holes through a circuit is created by the junction of two dissimilar semiconducting materials, one of which has a tendency to give up electrons and acquire holes (thereby becoming the positive, or *p*-type, charge carrier) while the other accepts electrons (becoming the negative, or *n*-type, carrier). The

electronic structure that permits this is the band gap; it is equivalent to the energy required to move an electron from the lower band to the higher. The magnitude of this gap is important. Only photons with energy greater than that of the band gap can excite electrons from the valence band to the conduction band; therefore, the smaller the gap, the more efficiently light will be converted to electricity—since there is a greater range of light frequencies with sufficiently high energies. On the other hand, the gap cannot be too small, because the electrons and holes then find it easy to recombine, and a sizable current cannot be maintained.

Maximum efficiency of the solar cell

The band gap defines the theoretical maximum efficiency of a solar cell, but this cannot be attained because of other materials factors. For each material there is an intrinsic rate of recombination of electrons and holes that removes their contribution to electric current. This recombination is enhanced by surfaces, interfaces, and crystal defects such as grain boundaries, dislocations, and impurities. Also, a fraction of the light is reflected by the cell's surface rather than being absorbed, and some can pass through the cell without exciting electrons to the conduction band.

Improvements in the trade-off between cell efficiency and cost are well illustrated by the preparation of silicon that is the basic material of current solar cells. Initially, high-purity silicon was grown from a silicon melt by slowly pulling out a seed crystal that grew by the accretion and slow solidification of the molten material. Known as the Czochralski process, this resulted in a high-purity, single-crystal ingot that was then sliced into wafers about 1 millimetre (0.04 inch) thick. Each wafer's surface was then "doped" with impurities to create *p*-type and *n*-type materials with a junction between them. Metal was then deposited to provide electrical leads, and the wafer was encapsulated to yield a cell about 100 millimetres in diameter. This was an expensive and time-consuming process; it has been much improved in a variety of ways. For example, high-purity silicon can be made at drastically reduced cost by chemically converting ordinary silicon to silane or trichlorosilane and then reducing it back to silicon. This silane process is capable of continuous operation at a high production rate and with low energy input. In order to avoid the cost and waste associated with sawing silicon into wafers, methods of directly drawing molten silicon into thin sheets or ribbons have been developed; these can produce crystalline, polycrystalline, or amorphous material. Another alternative is the manufacture of thin films on ceramic substrates—a process that uses much less silicon than other methods. Single-crystal silicon has a higher efficiency than other forms, but it is also much more expensive. The materials challenge is to find a combination of cost and efficiency that makes photovoltaic electricity economically possible.

Surface treatments that increase efficiency include deposition of antireflecting coatings, such as silicon nitride, on the front of the cell and highly reflective coatings on the rear. Thus, more of the light that strikes a cell actually enters it, and light that escapes out the back is reflected back into the cell. An ingenious surface treatment is part of the point contact method, in which the surface of the cell is not planar but microgrooved so that light is randomly reflected as it strikes the cell. This increases the amount of light that can be captured by the cell. (L.A.G.)

Materials for ground transportation

Reducing weight, emissions, and fuel consumption

The global effort to improve the efficiency of ground transportation vehicles, such as automobiles, buses, trucks, and trains, and thereby reduce the massive amounts of pollutants they emit, provides an excellent context within which to illustrate how materials science functions to develop new or better materials in response to critical human needs. For the automobile industry in particular, the story is a fascinating one in which the desire for lower vehicle weight, reduced emissions, and improved fuel economy has led to intense competition among aluminum, plastics, and steel companies for shares in the enormous markets involved (40 million to 50 million cars and trucks per year worldwide). In this battle, materials scientists have a key role to play because the success of their efforts to develop improved materials will determine the shape and viability of future automobiles.

Just how seriously suppliers to the industry view the need either to protect or to increase their share of these enormous markets is demonstrated by their establishing of special programs, consortia, or centres that are specifically designed to develop better alloys, plastics, or ceramics for automotive applications. For example, in the United States a program at the Aluminum Company of America (Alcoa) called the aluminum intensive vehicle (AIV), and a similar one at Reynolds Metals, were established to develop materials and processes for making automobile "space frames" consisting of aluminum-alloy rods and die-cast connectors joined by welding and adhesive bonding. Not to be outdone, another aluminum company, Alcan Aluminium Limited of Canada, in a program entitled aluminum structured vehicle technology (ASVT), began to investigate the construction of automobile unibodies from adhesively bonded aluminum sheet. The plastics industry, of course, has a powerful interest in replacing as many metal automobile components as possible, and in order to help bring this about a centre called D&S Plastics International was formed in the Detroit, Mich., area of the United States by three corporations. The specific aim of this centre was to develop materials and a process suitable for forming several connected panels or components (*e.g.*, body panels and bumper fascias) simultaneously out of different types of plastics. The centrepiece of the operation was a 4,000-ton co-injection press that could lead to cost reductions as great as 50 percent and thereby make the use of plastics for automotive applications more attractive.

In programs such as these, and in many more carried out by vendors and within the automobile companies themselves, materials scientists with specialized training in advanced metals, plastics, and ceramics have been leading a revolution in the automotive industry. The following sections describe specific needs that have been identified for improving the performance of automobiles and other ground-transportation vehicles, as well as approaches that materials scientists have taken in response to those needs.

METALS

Aluminum. Since aluminum has about one-third the density of steel, its substitution for steel in automobiles would seem to be a sensible approach to reducing weight and thereby increasing fuel economy and reducing harmful emissions. Such substitutions cannot be made, however, without due consideration of significant differences in other properties of the two materials. This is one important facet of the materials scientist's job—to help evaluate the suitability of a material for a given application based on how its properties balance against load and performance requirements specified by the design engineer. In this case (aluminum versus steel), it is instructive to consider the materials scientist's approach to evaluating the use of aluminum in automotive panels—such components as doors, hoods, trunk decks, and roofs that can make up more than 60 percent of a vehicle's weight.

Maximizing yield strength and elastic modulus

Two primary properties of any metal are (1) its yield strength, defined as its ability to resist permanent deformation (such as a fender dent), and (2) its elastic modulus, defined as its ability to resist elastic or springy deflection like a drum head. By alloying, aluminum can be made to have a yield strength equal to a moderately strong steel and therefore to exhibit similar resistance to denting in an automobile panel. On the other hand, alloying does not normally affect the elastic modulus of metals significantly, so that automotive door panels or hoods made from aluminum alloys, all of which have approximately one-third the modulus of steel, would be floppy and suffer large deflections when buffeted by the wind, for example. From this point of view, aluminum would appear to be a marginal choice for body panels.

One might attempt to overcome this deficiency by increasing the thickness of the aluminum sheet stock to three times the thickness of the steel it is intended to replace. This, however, would simply increase the weight to roughly that of an equivalent steel structure and thus

defeat the purpose of the exercise. Fortunately, as was elegantly demonstrated in 1980 by two British materials scientists, Michael Ashby and David Jones, when proper account is taken of the way an actual door panel deflects, constrained as it is by the door edges, it is possible to use aluminum sheet only slightly thicker than the steel it would replace and still achieve equivalent performance. The net result would be a weight savings of almost two-thirds by the substitution of aluminum for steel on such body components. This suggests that understanding the interrelationship between materials properties and structural design is an important factor in the successful application of materials science.

Another important activity of the materials scientist is that of alloy development, which in some cases involves designing alloys for very specific applications. For example, in Alcoa's AIV effort, materials scientists and engineers developed a special casting alloy for use as cast aluminum nodes (connecters) in their space frame design. Ordinarily, metal castings exhibit very little toughness, or ductility, and they are therefore prone to brittle fracture followed by catastrophic failure. Since the integrity of an automobile would be limited by having relatively brittle body components, a proprietary casting alloy and processing procedure were developed that provide a material of much greater ductility than is normally available in a casting alloy.

Many other advances in aluminum technology, brought about by materials scientists and design engineers, have led to a greater acceptance of aluminum in automobiles, trucks, buses, and even light rail vehicles. Among these are alloys for air-conditioner components that are designed to be chemically compatible with environmentally safer refrigerants and to withstand the higher pressures required by them. Also, alloys have been developed that combine good formability and corrosion resistance with the ability to achieve maximum strength without heat treating; these alloys develop their strength during the forming operation.

The growing use of aluminum

As a consequence, the list of vehicles that contain significant quantities of aluminum substituted for steel has steadily grown. A milestone was reached in 1992 with a limited-edition Jaguar sports car that was virtually all aluminum, including the engine, adhesively bonded chassis, and skin. Somewhat less expensive and in full production were Honda's Acura NSX, containing more than 400 kilograms (900 pounds) of aluminum compared with about 70 kilograms for the average automobile, and General Motors' Saturn, with an aluminum engine block and cylinder heads. These vehicles and others took their place alongside the British Land Rover, which was built with all-aluminum body panels beginning in 1948—a choice dictated by a shortage of steel during World War II and continued by the manufacturer ever since.

Steel. While the goal of the aluminum and plastics industries is to achieve vehicle weight reductions by substituting their products for steel components, the goal of the steel industry is to counter such inroads with such innovative developments as high-strength, but inexpensive, "microalloyed" steels that achieve weight savings by thickness reductions. In addition, alloys have been developed that can be tempered (strengthened) in paint-baking ovens rather than in separate and expensive heat-treatment furnaces normally required for conventional steels.

The microalloyed steels, also known as high-strength low-alloy (HSLA) steels, are intermediate in composition between carbon steels, whose properties are controlled mainly by the amount of carbon they contain (usually less than 1 percent), and alloy steels, which derive their strength, toughness, and corrosion resistance primarily from other elements, including silicon, nickel, and manganese, added in somewhat larger amounts. Developed in the 1960s and resurrected in the late 1970s to satisfy the need for weight savings through greater strength, the HSLA steels tend to be low in carbon with minute additions of titanium or vanadium, for example. Offering tensile strengths that can be triple the value of the carbon steels they are designed to replace (*e.g.,* 700 megapascals versus 200 megapascals), they have led to significant weight savings through thickness reductions—albeit at a slight loss of structural stiffness, because their elastic moduli are the same as other steels. They are considered to be quite competitive with aluminum substitutes for two reasons: they are relatively inexpensive (steel sells for one-half the price of aluminum on a per-unit-weight basis); and very little change in fabrication and processing procedures is needed in switching from carbon steel to HSLA steel, whereas major changes are usually required in switching to aluminum.

Bake-hardenable steels

Bake-hardenable steels were developed specifically for the purpose of eliminating an expensive fabrication step—*i.e.,* the heat-treating furnace, where steels are imparted with their final strength. To do this, materials scientists have designed steels that can be strengthened in the same ovens used to bake body paint onto the part. These furnaces must operate at relatively low temperatures (170° C, or 340° F), so that special steels had to be developed that would achieve suitable strengths at heat-treatment temperatures very much below those normally employed (up to 600° C, or 1,100° F). Knowing that high-alloy steels would never be hardenable at such low temperatures, materials scientists focused their attention on carbon steels, but even here adequate strengths could not be obtained initially. Then in the 1980s scientists at the Japanese Sumitomo Metal Industries developed a steel containing nitrogen (a gas that constitutes three-quarters of the Earth's atmosphere) in addition to carbon and several other additives. Very high strengths (over 900 megapascals) and excellent toughness can be achieved on formed parts with this inexpensive addition after baking for 20 minutes at temperatures typical for a paint-baking operation.

PLASTICS AND COMPOSITES

The motive for replacing the metal components of cars, trucks, and trains with plastics is the expectation of large weight savings due to the large differences in density involved: plastics are one-sixth the weight of steel and one-half that of aluminum per unit volume. However, as in evaluating the suitability of replacing steel with aluminum, the materials scientist must compare other properties of the materials in order to determine whether the tradeoffs are reasonable. For two reasons, the likely conclusion would be that plastics simply are not suitable for this type of application: the strength of most plastics, such as epoxies and polyesters, is roughly one-fifth that of steel or aluminum; and their elastic modulus is one-sixtieth that of steel and one-twentieth that of aluminum. On this basis, plastics do not appear to be suitable for structural components. What, then, accounts for the successful use that has been made of them? The answer lies in efforts made over the years by materials scientists, polymer chemists, mechanical engineers, and production managers to combine relatively weak and low-stiffness resins with high-strength, high-modulus reinforcements, thereby making new materials called composites with much more suitable properties than plastics alone.

The reinforcements used in composites are generally chosen for their high strength and modulus, as might be expected, but economic considerations often force compromises. For example, carbon fibres have extremely high modulus values (up to five times that of steel) and therefore make excellent reinforcements. However, their cost precludes their extensive use in automobiles, trucks, and trains, although they are used regularly in the aerospace industry. More suitable for non-aerospace applications are glass fibres (whose modulus can approach 1.5 times that of aluminum) or, in somewhat special cases, a mixture of glass and carbon fibres.

Long-fibre reinforcement

The physical form and shape of the reinforcements vary greatly, depending on many factors. The most effective reinforcements are long fibres, which are employed either in the form of a woven cloth or as separate layers of unidirectional fibres stacked upon one another until the proper laminate thickness is achieved. The resin may be applied to the fibres or cloth before laying up, thus forming what are termed prepregs, or it may be added later by "wetting out" the fibres. In either case, the assembly is then cured, usually under pressure, to form the composite. This type of composite takes full advantage of the properties of the fibres and is therefore capable of yielding strong, stiff

panels. Unfortunately, the labour involved in the lay-up operations and other factors make it very expensive, so that long-fibre reinforcement is used only sparingly in the automobile industry.

One attempt to avoid expensive hand lay-up operations involves chopped fibres that are employed in mat form, somewhat like felt, or as loose fibres that may be either blown into a mold or injected into a mold along with the resin. Another method does not use fibres at all; instead the reinforcement is in the form of small, high-modulus particles. These are the least expensive of all to process, since the particles are simply mixed into the resin, and the mixture is used in various types of molds. On the other hand, particles are the least efficient reinforcement material; as a consequence, property improvements are not outstanding.

In choosing the other major constituent in composites, the polymer matrix, one faces a somewhat daunting variety, including epoxies, polyimides, polyurethanes, and polyesters. Each has its advantages and disadvantages that must be evaluated in order to determine suitability for a particular application. Among the factors to be considered are cost, processing temperature (curing temperature if using a thermoset polymer and melting temperature if using a thermoplastic), flow properties in the molding operation, sag resistance during paint bake out, moisture resistance, and shelf life. The number of combinations of resins, reinforcements, production methods, and fibre-to-resin ratios is so challenging that materials scientists must join forces with polymer chemists and engineers from the design, production, and quality-control departments of the company in order to choose the right combination for the application.

Judging by the inroads that have been made in replacing metals with composites, it appears that technologists have been making the right choices. The introduction of fibreglass-reinforced plastic skins on General Motors' 1953 Corvette sports car marked the first appearance of composites in a production model, and composites have continued to appear in automotive components ever since. In 1984, General Motors' Fiero was placed on the market with the entire body made from composites, and the Camaro/Firebird models followed with doors, roof panels, fenders, and other parts made of composites. Composites were also chosen for exterior panels in the Saturn, which appeared in 1990. In addition, they have had less visible applications—for example, the glass-reinforced nylon air-intake manifold on some BMW models.

CERAMICS

Ceramics play an important role in engine efficiency and pollution abatement in automobiles and trucks. For example, one type of ceramic, cordierite (a magnesium aluminosilicate), is used as a substrate and support for catalysts in catalytic converters. It was chosen for this purpose because, along with many ceramics, it is lightweight, can operate at very high temperatures without melting, and conducts heat poorly (helping to retain exhaust heat for improved catalytic efficiency). In a novel application of ceramics, a cylinder wall was made of transparent sapphire (aluminum oxide) by General Motors' researchers in order to examine visually the internal workings of a gasoline engine combustion chamber. The intention was to arrive at improved understanding of combustion control, leading to greater efficiency of internal-combustion engines.

Ceramics in catalytic converters

Another application of ceramics to automotive needs is a ceramic sensor that is used to measure the oxygen content of exhaust gases. The ceramic, usually zirconium oxide to which a small amount of yttrium has been added, has the property of producing a voltage whose magnitude depends on the partial pressure of oxygen surrounding the material. The electrical signal obtained from such a sensor is then used to control the fuel-to-air ratio in the engine in order to obtain the most efficient operation.

Because of their brittleness, ceramics have not been used as load-bearing components in ground-transportation vehicles to any great extent. The problem remains a challenge to be solved by materials scientists of the future.

(J.D.V.)

Materials for aerospace

The primary goal in the selection of materials for aerospace structures is the enhancement of fuel efficiency to increase the distance traveled and the payload delivered. This goal can be attained by developments on two fronts: increased engine efficiency through higher operating temperatures and reduced structural weight. In order to meet these needs, materials scientists look to materials in two broad areas—metal alloys and advanced composite materials. A key factor contributing to the advancement of these new materials is the growing ability to tailor materials to achieve specific properties.

Enhancing fuel efficiency

METALS

Many of the advanced metals currently in use in aircraft were designed specifically for applications in gas-turbine engines, the components of which are exposed to high temperatures, corrosive gases, vibration, and high mechanical loads. During the period of early jet engines (from about 1940 to 1970), design requirements were met by the development of new alloys alone. But the more severe requirements of advanced propulsion systems have driven the development of novel alloys that can withstand temperatures greater than 1,000° C (1,800° F), and the structural performance of such alloys has been improved by developments in the processes of melting and solidification.

Melting and solidifying. Alloys are substances composed of two or more metals or of a metal and a nonmetal that are intimately united, usually by dissolving in each other when they are melted. The principal objectives of melting are to remove impurities and to mix the alloying ingredients homogeneously in the base metal. Major advances have been made with the development of new processes based on melting under vacuum (hot isostatic pressing), rapid solidification, and directional solidification.

In hot isostatic pressing, prealloyed powders are packed into a thin-walled, collapsible container, which is placed in a high-temperature vacuum to remove adsorbed gas molecules. It is then sealed and put in a press, where it is exposed to very high temperatures and pressures. The mold collapses and welds the powder together in the desired shape.

Molten metals cooled at rates as high as a million degrees per second tend to solidify into a relatively homogeneous microstructure, since there is insufficient time for crystalline grains to nucleate and grow. Such homogeneous materials tend to be stronger than the typical "grainy" metals. Rapid cooling rates can be achieved by "splat" cooling, in which molten droplets are projected onto a cold surface. Rapid heating and solidification can also be achieved by passing high-power laser beams over the material's surface.

Unlike composite materials (see below), grainy metals exhibit properties that are essentially the same in all directions, so they cannot be tailored to match anticipated load paths (*i.e.,* stresses applied in specific directions). However, a technique called directional solidification provides a certain degree of tailorability. In this process the temperature of the mold is precisely controlled to promote the formation of aligned stiff crystals as the molten metal cools. These serve to reinforce the component in the direction of alignment in the same fashion as fibres reinforce composite materials.

Alloying. These advances in processing have been accompanied by the development of new "superalloys." Superalloys are high-strength, often complex alloys that are resistant to high temperatures and severe mechanical stress and that exhibit high surface stability. They are commonly classified into three major categories: nickel-based, cobalt-based, and iron-based. Nickel-based superalloys predominate in the turbine section of jet engines. Although they have little inherent resistance to oxidation at high temperatures, they gain desirable properties through the addition of cobalt, chromium, tungsten, molybdenum, titanium, aluminum, and niobium.

Superalloys

Aluminum-lithium alloys are stiffer and less dense than conventional aluminum alloys. They are also "superplas-

tic," owing to the fine grain size that can now be achieved in processing. Alloys in this group are appropriate for use in engine components exposed to intermediate to high temperatures; they can also be used in wing and body skins.

Titanium alloys, as modified to withstand high temperatures, are seeing increased use in turbine engines. They are also employed in airframes, primarily for military aircraft but to some extent for commercial planes as well.

COMPOSITES

While developments in metals have had an impact on engine design, there is a growing trend toward the application of composite materials to aerospace structures. One of the reasons for this is that alloys do not offer substantial weight savings, which is a primary advantage of composites. Indeed, advanced composites have been used most widely where saving mass results in either significantly improved performance or significantly lower life-cycle costs. The most extensive application, therefore, has been in satellite systems, military aircraft, radomes, helicopters, commercial transport aircraft, and general aviation.

Broadly defined, composites are materials with two or more distinct components that combine to yield characteristics superior to those of the individual constituents. Although this definition can apply to such ordinary building materials as plywood, concrete, and bricks, within the aerospace industry the term composite generally refers to the fibre-reinforced metal, polymer, and ceramic products that have come into use since World War II. These materials consist of fibres (such as glass, graphite, silicon carbide, or aramid) that are embedded in a matrix of, for example, aluminum, epoxy, or silicon nitride.

In the late 1950s a revolution in materials development occurred in response to the space program's need for lightweight, thermally stable materials. Boron-tungsten filaments, carbon-graphite fibres, and organic aramid fibres proved to be strong, stiff, and light, but one problem with using them as fibres was that they were of limited value in any construction other than rope, which can bear loads in only one direction. Materials scientists needed to develop a way to make them useful under all loading conditions, and this led to the development of composites. While the structural value of a bundle of fibres is low, the strength of individual fibres can be harnessed if they are embedded in a matrix that acts as an adhesive, binding the fibres and lending solidity to the material. The matrix also protects the fibres from environmental stress and physical damage, which can initiate cracks. In addition, while the strength and stiffness of the composite remain largely a function of the reinforcing material—that is, the fibres—the matrix can contribute other properties, such as thermal and electrical conductivity and, most important, thermal stability. Finally, fibre-matrix combination reduces the potential for complete fracture. In a monolithic (or single) material, a crack, once started, generally continues to propagate until the material fails; in a composite, if one fibre in an assemblage fails, the crack may not extend to the other fibres, so the damage is limited.

Contributions of fibre reinforcement and the matrix

To some extent, the composite-materials engineer is trying to mimic structures made spontaneously by plants and animals. A tree, for example, is made of a fibre-reinforced material whose strength is derived from cellulose fibres that grow in directions that match the weight of the branches. Similarly, many organisms naturally fabricate "bioceramics," such as those found in shells, teeth, and bones. While the designers of composites for the aerospace industry would like to copy some of the features of bioceramics production—room-temperature processing and net-shape products, for example—they do not want to be constrained by slow processing methods and limited fibre and matrix material choices. In addition, unlike a mollusk, which has to produce only one shell, the composites manufacturer has to use rapid, repeatable processing methods that can fabricate hundreds or even thousands of parts.

Modern composites are generally classified into three categories according to the matrix material: polymer, metal, or ceramic. Since polymeric materials tend to degrade at elevated temperatures, polymer-matrix composites (PMCs) are restricted to secondary structures in which operating temperatures are lower than 300° C (570° F). For higher temperatures, metal-matrix and ceramic-matrix composites are required.

Polymer-matrix composites. PMCs are of two broad types, thermosets and thermoplastics. Thermosets are solidified by irreversible chemical reactions, in which the molecules in the polymer "cross-link," or form connected chains. The most common thermosetting matrix materials for high-performance composites used in the aerospace industry are the epoxies. Thermoplastics, on the other hand, are melted and then solidified, a process that can be repeated numerous times for reprocessing. Although the manufacturing technologies for thermoplastics are generally not as well developed as those for thermosets, thermoplastics offer several advantages. First, they do not have the shelf-life problem associated with thermosets, which require freezer storage to halt the irreversible curing process that begins at room temperature. Second, they are more desirable from an environmental point of view, as they can be recycled. They also exhibit higher fracture toughness and better resistance to solvent attack. Unfortunately, thermoplastics are more expensive, and they generally do not resist heat as well as thermosets; however, strides are being made in developing thermoplastics with higher melting temperatures. Overall, thermoplastics offer a greater choice of processing approaches, so that the process can be determined by the scale and rate of production required and by the size of the component.

Thermosets and thermoplastics

A variety of reinforcements can be used with both thermoset and thermoplastic PMCs, including particles, whiskers (very fine single crystals), discontinuous (short) fibres, continuous fibres, and textile preforms (made by braiding, weaving, or knitting fibres together in specified designs). Continuous fibres are more efficient at resisting loads than are short ones, but it is more difficult to fabricate complex shapes from materials containing continuous fibres than from short-fibre or particle-reinforced materials. To aid in processing, most high-performance composites are strengthened with filaments that are bundled into yarns. Each yarn, or tow, contains thousands of filaments, each of which has a diameter of approximately 10 micrometres (0.01 millimetre, or 0.0004 inch).

Depending on the application and on the type of load to be applied to the composite part, the reinforcement can be random, unidirectional (aligned in a single direction), or multidirectional (oriented in two or three dimensions). If the load is uniaxial, the fibres are all aligned in the load direction to gain maximum benefit of their stiffness and strength. However, for multidirectional loading (for example, in aircraft skins), the fibres must be oriented in a variety of directions. This is often accomplished by stacking layers (or lamina) of continuous-fibre systems.

The most common form of material used for the fabrication of composite structures is the preimpregnated tape, or "prepreg." There are two categories of prepreg: tapes, generally 75 millimetres (3 inches) or less in width, intended for fabrication in automated, computer-controlled tape-laying machines; and "broad goods," usually several metres in dimension, intended for hand lay-up and large sheet applications. To make prepregs, fibres are subjected to a surface treatment so that the resin will adhere to them. They are then placed in a resin bath and rolled into tapes or sheets.

To fabricate the composite, the manufacturer "lays up" the prepreg according to the reinforcement needs of the application. This has traditionally been done by hand, with successive layers of a broad-goods laminate stacked over a tool in the shape of the desired part in such a way as to accommodate the anticipated loads. However, efforts are now being directed toward automated fibre-placement methods in order to reduce costs and ensure quality and repeatability. Automated fibre-placement processes fall into two categories, tape laying and filament winding. The tape-laying process involves the use of devices that control the placement of narrow prepreg tapes over tooling with the contours of the desired part and along paths prescribed by the design requirements of the structure. The width of the tape determines the "sharpness" of the turns required

Fabricating a composite structure

to place the fibres in the prescribed direction—*i.e.*, wide tapes are used for gradual turns, while narrow tapes are required for the sharp turns associated with more complex shapes.

Filament winding uses the narrowest prepreg unit available—the yarn, or tow, of impregnated filaments. In this process, the tows are wound in prescribed directions over a rotating mandrel in the shape of the part. Successive layers are added until the required thickness is reached. Although filament winding was initially limited to geodesic paths (*i.e.*, winding the fibres along the most direct route between two points), the process is now capable of fabricating complex shapes through the use of robots.

For thermosetting polymers, the structure generated by either tape laying or filament winding must undergo a second manipulation in order to solidify the polymer through a curing reaction. This is usually accomplished by heating the completed structure in an autoclave, or oven. Thermoplastic systems offer the advantage of on-line consolidation, so that the high energy and capital costs associated with the curing step can be eliminated. For these systems, prepreg can be locally melted, consolidated, and cooled at the point of contact so that a finished structure is produced. A variety of energy sources are used to concentrate heat at the point of contact, including hot-gas torches, infrared light, and laser beams.

Pultrusion, the only truly continuous process for manufacturing parts from PMCs, is economical but limited to the production of beamlike shapes. On a pultrusion line, fibres and the resin are pushed through a heated die, or shaping tool, at one end, then cooled and pulled out at the other end. This process can be applied to both thermoplastic and thermoset polymers.

Resin transfer molding, or RTM, is a composites processing method that offers a high potential for tailorability but is currently limited to low-viscosity (easily flowing) thermosetting polymers. In RTM, a textile preform—made by braiding, weaving, or knitting fibres together in a specified design—is placed into a mold, which is then closed and injected with a resin. After consolidation, the mold is opened and the part removed. Preforms can be made in a wide variety of architectures, and several can be joined together during the RTM process to form a multi-element preform offering reinforcement in specific areas and load directions.

Forming of thermoplastic sheets

The similarity of meltable thermoplastic polymers to metals has prompted the extension of techniques used in metalworking. Sheet forming, used since the 19th century by metallurgists, is now applied to the processing of thermoplastic composites. In a typical thermoforming process, the sheet stock, or preform, is heated in an oven. At the forming temperature, the sheet is transferred into a forming system, where it is forced to conform to a tool, with a shape that matches the finished part. After forming, the sheet is cooled under pressure and then removed. Stretch forming, a variation on thermoplastic sheet forming, is specifically designed to take advantage of the extensibility, or ability to be stretched, of thermoplastics reinforced with long, discontinuous fibres. In this process, a straight preconsolidated beam is heated and then stretched over a shaped tool to introduce curvature. The specific advantage of stretch forming is that it provides an automated way to achieve a very high degree of fibre-orientation control in a wide range of part sizes.

Metal-matrix and ceramic-matrix composites. The requirement that finished parts be able to operate at temperatures high enough to melt or degrade a polymer matrix creates the need for other types of matrix materials, often metals. Metal matrices offer not only high-temperature resistance but also strength and ductility, or "bendability," which increases toughness. The main problems with metal-matrix composites (MMCs) are that even the lightest metals are heavier than polymers, and they are very complex to process. MMCs can be used in such areas as the skin of a hypersonic aircraft, but on wing edges and in engines temperatures often exceed the melting point of metals. For the latter applications, ceramic-matrix composites (CMCs) are seeing increasing use, although the technology for CMCs is less mature than that for PMCs. Ceramics consist of alumina, silica, zirconia, and other elements refined from fine earth and sand or of synthetic materials, such as silicon nitride or silicon carbide. The desirable properties of ceramics include superior heat resistance and low abrasive and corrosive properties. Their primary drawback is brittleness, which can be reduced by reinforcing with fibres or whiskers. The reinforcement material can be a metal or another ceramic.

Unlike polymers and metals, which can be processed by techniques that involve melting (or softening) followed by solidification, high-temperature ceramics cannot be melted. They are generally produced by some variation of sintering, a technique that renders a combination of materials into a coherent mass by heating to high temperatures without complete melting. If continuous fibres or textile weaves (as opposed to short fibres or whiskers) are involved, sintering is preceded by impregnating the assembly of fibres with a slurry of ceramic particles dispersed in a liquid. A major benefit of using CMCs in aircraft engines is that they allow higher operating temperatures and thus greater combustion efficiency, leading to reduced fuel consumption. An additional benefit is derived from the low density of CMCs, which translates into substantial weight savings.

Carbon-carbon composites

Other advanced composites. Carbon-carbon composites are closely related to CMCs but differ in the methods by which they are produced. Carbon-carbon composites consist of semicrystalline carbon fibres embedded in a matrix of amorphous carbon. The composite begins as a PMC, with semicrystalline carbon fibres impregnated with a polymeric phenolic resin. The resin-soaked system is heated in an inert atmosphere to pyrolyze, or char, the polymer to a carbon residue. The composite is re-impregnated with polymer, and the pyrolysis is repeated. Continued repetition of this impregnation/pyrolysis process yields a structure with minimal voids. Carbon-carbon composites retain their strength at 2,500° C (4,500° F) and are used in the nose cones of reentry vehicles. However, because they are vulnerable to oxidation at such high temperatures, they must be protected by a thin layer of ceramic.

While materials research for aerospace applications has focused largely on mechanical properties such as stiffness and strength, other attributes are important for use in space. Materials are needed with a near-zero coefficient of thermal expansion; in other words, they have to be thermally stable and should not expand and contract when exposed to extreme changes in temperature. A great deal of research is focused on developing such materials for high-speed civilian aircraft, where thermal cycling is a major issue. High-toughness materials and nonflammable resin composite systems are also under investigation to improve the safety of aircraft interiors.

Efforts are also being directed toward the development of "smart," or responsive, materials. Representing another attempt to mimic certain characteristics of living organisms, smart materials, with their built-in sensors and actuators, would react to their external environment by bringing on a desired response. This would be done by linking the mechanical, electrical, and magnetic properties of these materials. For example, piezoelectric materials generate an electrical current when they are bent; conversely, when an electrical current is passed through these materials, they stiffen. This property can be used to suppress vibration: the electrical current generated during vibration could be detected, amplified, and sent back, causing the material to stiffen and stop vibrating. (R.L.McC./D.S.K.)

Materials for computers and communications

The basic function of computers and communications systems is to process and transmit information in the form of signals representing data, speech, sound, documents, and visual images. These signals are created, transmitted, and processed as moving electrons or photons, and so the basic materials groups involved are classified as electronic and photonic. In some cases, materials known as optoelectronic bridge these two classes, combining abilities to interact usefully with both electrons and photons.

Among the electronic materials are various crystalline

semiconductors; metalized film conductors; dielectric films; solders; ceramics and polymers formed into substrates on which circuits are assembled or printed; and gold or copper wiring and cabling.

Photonic materials include a number of compound semiconductors designed for light emission or detection; elemental dopants that serve as photonic performance-control agents; metal- or diamond-film heat sinks; metalized films for contacts, physical barriers, and bonding; and silica glass, ceramics, and rare earths for optical fibres.

ELECTRONIC MATERIALS

Between 1955 and 1990, improvements and innovations in semiconductor technology increased the performance and decreased the cost of electronic materials and devices by a factor of one million—an achievement unparalleled in the history of any technology. Along with this extraordinary explosion of technology has come an exponentially upward spiral of the capital investment necessary for manufacturing operations. In order to maintain cost-effectiveness and flexibility, radical changes in materials and manufacturing operations will be necessary.

Semiconductor crystals. *Silicon.* Bulk semiconductor silicon for the manufacture of integrated circuits (sometimes referred to as electronic-grade silicon) is the purest material ever made commercially in large quantities. One of the most important factors in preparing this material is control of such impurities as boron, phosphorus, and carbon (not to be confused with the dopants added later during circuit production). For the ultimate levels of integrated-circuit design, stray contaminant atoms must constitute less than 0.1 part per trillion of the material.

Control of impurities

For fabrication into integrated circuits, bulk semiconductor silicon must be in the form of a single-crystal material with high crystalline perfection and the desired charge-carrier concentration. The size of the silicon ingot, or boule, has been scaled up in recent years, in order to provide wafers of increasing diameter that are demanded by the economics of integrated-circuit manufacturing. Most commonly, a 60-kilogram (130-pound) charge is grown to an ingot with a diameter of 200 millimetres (8 inches), but the semiconductor industry will soon require ingots as large as 300 millimetres. The ingots are then converted into wafers by machining and chemical processes.

III–V compounds. Although silicon is by far the most commonly used crystal material for integrated circuits, a significant volume of semiconductor devices and circuits employs III–V technology, so named because it is based on crystalline compounds formed by combining metallic elements from column III and nonmetallic elements from column V of the periodic table of chemical elements. When the elements are gallium and arsenic, the semiconductor is called gallium arsenide, or GaAs. However, other elements such as indium, phosphorus, and aluminum are often used in the compound to achieve specific performance characteristics.

For electronic applications, the III–V semiconductors offer the basic advantage of higher electron mobility, which translates into higher operating speeds. In addition, devices made with III–V compounds provide lower voltage operation for specific functions, radiation hardness (especially important for satellites and space vehicles), and semi-insulating substrates (avoiding the presence of parasitic capacitance in switching devices).

III–V materials are more difficult to handle than silicon, and a III–V wafer or substrate usually is less than half the size of a silicon wafer. In addition, a gallium arsenide wafer entering the processing facility can be expected to cost 10 to 20 times as much as a silicon wafer, although that cost difference narrows somewhat after fabrication, packaging, and testing. Nevertheless, there is one major characteristic of III–V materials with which silicon cannot compete: a III–V compound can be tailored to generate or detect photons of a specific wavelength. For example, an indium gallium arsenide phosphide (InGaAsP) laser can generate radiation at 1.55 micrometres to carry digitally coded information streams. (See below *Photonic materials.*) This means that a III–V component can fill both electronic and photonic functions in the same integrated circuit.

Photoresist films. Patterning polished wafers with an integrated circuit requires the use of photoresist materials that form thin coatings on the wafer before each step of the photolithographic process. Modern photoresists are polymeric materials that are modified when exposed to radiation (either in the form of visible, ultraviolet, or X-ray photons or in the form of energetic electron beams). A photoresist typically contains a photoactive compound (PAC) and an alkaline-soluble resin. The PAC, mixed into the resin, renders it insoluble. This mixture is coated onto the semiconductor wafer and is then exposed to radiation through a "mask" that carries the desired pattern. Exposed PAC is converted into an acid that renders the resin soluble, so that the resist can be dissolved and the exposed substrate beneath it chemically etched or metallically coated to match the circuit design.

Photo-active compound

Besides practical properties such as shelf life, cost, and availability, the key properties of a photoresist include purity, etching resistance, resolution, contrast, and sensitivity. As the feature sizes of integrated circuits shrink in each successive generation of microchips, photoresist materials are challenged to handle shorter wavelengths of light. For example, the photolithography of current designs (with features that have shrunk to less than one micrometre) is based on ultraviolet radiation in the wavelength range of 365 to 436 nanometres, but, in order to define accurately the smaller features of future microchips (less than 0.25 micrometre), shorter wavelengths will be necessary. The problem here is that electromagnetic radiation in such frequency regions is weaker. One solution is to use the chemically amplified photoresist, or CAMP. The sensitivity of a photoresist is measured by its quantum efficiency, or the number of chemical events that occur when a photon is absorbed by the material. In CAMP material, the number of events is dramatically increased by subsequent chemical reactions (hence the amplification), which means that less light is needed to complete the process.

Electric connections. The performance of today's electronic systems (and photonic systems as well) is limited significantly by interconnection technology, in which components and subsystems are linked by conductors and connectors. Currently, very fine gold or copper wiring, as thin as 30 micrometres, is used to carry electric current to and from the many pads along the sides or ends of a microchip to other components on a circuit board. The capacitance involved in such circuitry slows down the flow of electrons and, hence, of information. However, by integrating several chips into a single multichip module, in which the chips are connected on a shared substrate by various conducting materials (such as metalized film), the speed of information flow can be increased, thus improving the assembly's performance. Ideally, all the chips in a single module would be fabricated simultaneously on the same wafer, but in practice this is not feasible: Silicon crystal manufacture is still subject to an average of one flaw per wafer, meaning that at least one of the many chips cut from each wafer is scrapped. If the whole wafer area were dedicated to a single multifunction assembly, that one flaw would scrap the entire module. Multichip modules are therefore made up of as many as five microchips bonded to a silicon or ceramic substrate on which resistors and capacitors have been constructed with thin films. Typical materials used in a multichip module include the substrate; gold paste conductors applied in an additive process resembling silk screen printing; vitreous glazes to insulate the gold paste conductors from subsequent film layers; a series of thin films made with tantalum nitride, titanium, palladium, and plated gold; and a final package of silicone rubber.

Multichip modules

Packaging materials. Several major types of packaging material are used by the electronics industry, including ceramic, refractory glass, premolded plastic, and postmolded plastic. Ceramic and glass packages cost more than plastic packages, so they make up less than 10 percent of the worldwide total. However, they provide the best protection for complex chips. Premolded plastic packages account for only a small but important fraction of the market, since they are required for packaging devices with many leads. Most plastic packages are postmolded, meaning that the

package body is molded over the assembly after the microchip has been attached to the fan-out pattern.

Precursors. The starting materials for most semiconductor devices are volatile and ultrapure gaseous derivatives of various organic and inorganic precursors. Many of them are toxic, and many will ignite spontaneously in the atmosphere. These gases are transported in high-pressure cylinders from the plant where they were made to the site where they will be used. One possible method of replacing these precursors with materials that are environmentally safe is known as in situ synthesis. In this method, dangerous reagents would be generated on demand in only the desired quantities, instead of being shipped cross-country and stored until needed at the semiconductor processing plant.

PHOTONIC MATERIALS

Computers and communications systems have been dominated by electronic technology since their beginnings, but photonic technology is making serious inroads throughout the information movement and management systems with such devices as lasers, light-emitting diodes, photodetecting diodes, optical switches, optical amplifiers, optical modulators, and optical fibres. Indeed, for long-distance terrestrial and transoceanic transmission of information, photonics has almost completely displaced electronics.

Crystalline materials. The light detectors and generators listed above are actually optoelectronic, because they link photonic and electronic systems. They employ the III–V compound semiconductors described above, many of them characterized by their band gaps—*i.e.*, the energy minimum of the electron conduction band and the energy maximum of hole valence bands occur at the same location in the momentum space, allowing electrons and holes to recombine and radiate photons efficiently. (By contrast, the conduction band minimum and the valence band maximum in silicon have dissimilar momenta, and therefore the electrons and holes cannot recombine efficiently.) Among the important compounds are gallium arsenide, aluminum gallium arsenide, indium gallium arsenide phosphide, indium phosphide, and aluminum indium arsenide.

Band gap

Fabricating a single crystal from these combinations of elements is far more difficult than creating a single crystal of electronic-grade silicon. Special furnaces are required, and the process can take several days. Notwithstanding the precision involved, the sausage-shaped boule is less than half the diameter of a silicon ingot and is subject to a much higher rate of defects. Researchers are continuously seeking ways to reduce the thermal stresses that are primarily responsible for dislocations in the III–V crystal lattice that cause these defects. The purity and structural perfection of the final single-crystal substrates affect the qualities of the crystalline layers that are grown on them and the regions that are diffused or implanted in them during the manufacture of photonic devices.

Epitaxial layers. For the efficient emission or detection of photons, it is often necessary to constrain these processes to very thin semiconductor layers. These thin layers, grown atop bulk semiconductor wafers, are called epitaxial layers because their crystallinity matches that of the substrate even though the composition of the materials may differ—*e.g.*, gallium aluminum arsenide (GaAlAs) grown atop a gallium arsenide substrate. The resulting layers form what is called a heterostructure. Most continuously operating semiconductor lasers consist of heterostructures, a simple example consisting of 1000-angstrom thick gallium arsenide layers sandwiched between somewhat thicker (about 10000 angstroms) layers of gallium aluminum arsenide—all grown epitaxially on a gallium arsenide substrate. The sandwiching and repeating of very thin layers of a semiconductor between layers of a different composition allow one to modify the band gap of the sandwiched layer. This technique, called band-gap engineering, permits the creation of semiconductor materials with properties that cannot be found in nature. Band-gap engineering, used extensively with III–V compound semiconductors, can also be applied to elemental semiconductors such as silicon and germanium.

The most precise method of growing epitaxial layers on a semiconducting substrate is molecular-beam epitaxy (MBE). In this technique, a stream or beam of atoms or molecules is effused from a common source and travels across a vacuum to strike a heated crystal surface, forming a layer that has the same crystal structure as the substrate. Variations of MBE include elemental-source MBE, hydride-source MBE, gas-source MBE, and metal-organic MBE. Other approaches to epitaxial growth are liquid-phase epitaxy (LPE) or chemical vapour deposition (CVD). The latter method includes hydride CVD, trichloride CVD, and metal-organic CVD.

Molecular-beam epitaxy

Normally, epitaxial layers are grown on flat surfaces, but scientists are searching for an economical and reliable method of growing epitaxial material on nonplanar structures—for example, around the "mesas" or "ridges" or in the "tubs" or "channels" that are etched into the surface of semiconducting devices. Nonplanar epitaxy is considered necessary for producing monolithic integrated optical devices or all-photonic switches and logic elements, but mastery of this method requires better understanding of the surface chemistry and surface dynamics of epitaxial growth.

Optical switching. Research in this area is driven by the need to switch data streams of higher and higher speed efficiently as customers for computer and communications services demand transmission and switching rates far higher than can be provided by a purely electronic system. Thanks to developments in semiconductor lasers and detectors (described above) and in optical fibres (described below), transmission at the desired high speeds has become possible. However, the switching of optical data streams still requires converting the data from the optical to the electronic domain, subjecting them to electronic switching and to manipulation inside the switching apparatus, and then reconverting the switched and reconfigured data into the optical domain for transmission over optical fibres. Electronic switching therefore is seen as the principal barrier to achieving higher switching speeds. One approach to solving this problem would be to introduce optics inside digital switching machines. Known as free-space photonics, this approach would involve such devices as semiconductor lasers or light-emitting diodes (LEDs), optical modulators, and photodetectors—all of which would be integrated into systems combined with electronic components.

One commercially available device for photonic switching is the quantum-well self-electro-optic-effect device, or SEED. The key concept for this device is the use of quantum wells. These structures consist of many thin layers of two different semiconductor materials. Individual layers are typically 10 nanometres (about 40 atoms) thick, and 100 layers are used in a device about 1 micrometre thick. When a voltage is applied across the layers, the transmission of photons through the quantum wells changes significantly, in effect creating an optical modulator—an essential component of any photonic circuit. Variations on the SEED concept are the symmetric SEED (S-SEED) and the field-effect transistor SEED. Neighbouring S-SEEDs could be connected by pairs of back-to-back quantum-well photodiodes, and commercially sized interconnection networks could be built by using free-space photonic interconnections between two-dimensional arrays of switching nodes. However, even this type of free-space optical interconnection technology would only enhance and extend electronic technology, not replace it.

Quantum wells

The move of optoelectronic and photonic integrated circuits out of the research laboratory and into the marketplace has been made possible by the availability of high-quality epitaxial growth techniques for building up lattice-matched crystalline layers of indium gallium arsenide phosphide and indium phosphide (InGaAsP/InP). This III–V compound system is central to the light emitters and detectors used in the 1.3-micrometre and 1.5-micrometre wavelength ranges at which optical fibre has very low transmission loss.

Optical transmission. As the rates of transmission are increased from millions of bits (megabits) per second to billions of bits (gigabits) per second, commercially avail-

able lasers encounter a physical limitation called "chirping," in which the optical frequency of the laser begins to waver during a pulse. Future systems, which may require from 2.4 to 30 gigabits per second, are probably going to be based on the use of a continuously operating distributed-feedback laser, whose output will be modulated in intensity by passing it through a modulator. This device consists of a crystal substrate of lithium niobate onto which a titanium channel is diffused to function as a light guide. The signal is encoded onto the light beam via a microwave radio-frequency feed through neighbouring channels in the coupler. Such a device is used only at the transmitter end of the optical path.

Both communications and computer systems rely on silica glass fibres to transmit light signals from lasers and LEDs. For long-distance transmission, optical-fibre cables are usually equipped with electro-optical repeater assemblies approximately every 100 kilometres. A new approach, called optical amplifiers, has been developed for deployment in transoceanic fibre-optic cables. Unlike traditional repeaters, optical amplifiers work by adding photons to a light signal without changing it to an electrical signal and without changing its bit-rate. Since they can be used at any desired transmission bit-rate, a transoceanic cable equipped with these devices can be upgraded to higher bit-rates simply by changing the lasers and photodiodes at each end. No retrofitting of higher bit-rate amplifiers is necessary.

Amplifying optical transmissions

The optical amplifier is a module containing a semiconductor pump laser and a short length of optical fibre whose core has been doped with less than 0.1 percent erbium, an optically active rare-earth element. The pump laser is powered by an electrical conductor that runs the length of the cable. The amplifier functions by converting the optical energy generated by the pump source into signal photon energy. When a signal-carrying stream of laser pulses passes through the optical amplifier, it is combined with the pump light through a wavelength division multiplexer located in the module. The combined signal is fed through the erbium-doped fibre length, where the excited erbium ions contribute photons coherently to the signal. The amplified signal is then fed to the next section of cable for transmission to the next optical amplifier, perhaps 200 to 300 kilometres away. (C.K.N.P.)

Materials for medicine

The treatment of many human disease conditions requires surgical intervention in order to assist, augment, sustain, or replace a diseased organ, and such procedures involve the use of materials foreign to the body. These materials, known as biomaterials, include synthetic polymers and, to a lesser extent, biological polymers, metals, and ceramics. Specific applications of biomaterials range from high-volume products such as blood bags, syringes, and needles to more challenging implantable devices designed to augment or replace a diseased human organ. The latter devices are used in cardiovascular, orthopedic, and dental applications as well as in a wide range of invasive treatment and diagnostic systems. Many of these devices have made possible notable clinical successes. For example, in cardiovascular applications, thousands of lives have been saved by heart valves, heart pacemakers, and large-diameter vascular grafts, and orthopedic hip-joint replacements have shown great long-term success in the treatment of patients suffering from debilitating joint diseases. With such a tremendous increase in medical applications, demand for a wide range of biomaterials grows by 5 to 15 percent each year. In the United States the annual market for surgical implants exceeds $10 billion, approximately 10 percent of world demand.

Biocompatibility

Nevertheless, applications of biomaterials are limited by biocompatibility, the problem of adverse interactions arising at the junction between the biomaterial and the host tissue. Optimizing the interactions that occur at the surface of implanted biomaterials represents the most significant key to further advances, and an excellent basis for these advances can be found in the growing understanding of complex biological materials and in the development of novel biomaterials custom-designed at the molecular level for specific medical applications.

This section describes biomaterials that are used in medicine, with emphasis on polymer materials and on the challenges associated with implantable devices used in the cardiovascular and orthopedic areas.

GENERAL REQUIREMENTS OF BIOMATERIALS

Research on developing new biomaterials is an interdisciplinary effort, often involving collaboration among materials scientists and engineers, biomedical engineers, pathologists, and clinicians to solve clinical problems. The design or selection of a specific biomaterial depends on the relative importance of the various properties that are required for the intended medical application. Physical properties that are generally considered include hardness, tensile strength, modulus, and elongation; fatigue strength, which is determined by a material's response to cyclic loads or strains; impact properties; resistance to abrasion and wear; long-term dimensional stability, which is described by a material's viscoelastic properties; swelling in aqueous media; and permeability to gases, water, and small biomolecules. In addition, biomaterials are exposed to human tissues and fluids, so that predicting the results of possible interactions between host and material is an important and unique consideration in using synthetic materials in medicine. Two particularly important issues in biocompatibility are thrombosis, which involves blood coagulation and the adhesion of blood platelets to biomaterial surfaces, and the fibrous-tissue encapsulation of biomaterials that are implanted in soft tissues.

Poor selection of materials can lead to clinical problems. One example of this situation was the choice of silicone rubber as a poppet in an early heart valve design. The silicone absorbed lipid from plasma and swelled sufficiently to become trapped between the metal struts of the valve. Another unfortunate choice as a biomaterial was Teflon (trademark), which is noted for its low coefficient of friction and its chemical inertness but which has relatively poor abrasion resistance. Thus, as an occluder in a heart valve or as an acetabular cup in a hip-joint prosthesis, Teflon may eventually wear to such an extent that the device would fail. In addition, degradable polyesterurethane foam was abandoned as a fixation patch for breast prostheses, because it offered a distinct possibility for the release of carcinogenic by-products as it degraded.

The problem of additives

Besides their constituent polymer molecules, synthetic biomaterials may contain several additives, such as unreacted monomers and catalysts, inorganic fillers or organic plasticizers, antioxidants and stabilizers, and processing lubricants or mold-release agents on the material's surface. In addition, several degradation products may result from the processing, sterilization, storage, and ultimately implantation of a device. Many additives are beneficial—for example, the silica filler that is indispensable in silicone rubber for good mechanical performance or the antioxidants and stabilizers that prevent premature oxidative degradation of polyetherurethanes. Other additives, such as pigments, can be eliminated from biomedical products. Indeed, a "medical-grade" biomaterial is one that has had nonessential additives and potential contaminants excluded or eliminated from the polymer. In order to achieve this grade, the polymer may need to be solvent-extracted before use, thereby eliminating low-molecular-weight materials. Generally, additives in polymers are regarded with extreme suspicion, because it is often the additives rather than the constituent polymer molecules that are the source of adverse biocompatibility.

POLYMER BIOMATERIALS

The majority of biomaterials used in humans are synthetic polymers such as the polyurethanes or Dacron (trademark: chemical name polyethylene terephthalate), rather than polymers of biological origin such as proteins or polysaccharides. The common synthetic biomaterials and their applications are listed in Table 2. Their properties vary widely, from the soft and delicate water-absorbing hydrogels made into contact lenses to the resilient elastomers found in short- and long-term cardiovascular devices or

Table 2: Biomaterials and Their Applications

material and application	biomedical device
Cardiovascular applications	
Polypropylene (isotactic)	prosthetic heart valve structures; sutures
Polytetrafluoroethylene	vascular grafts; catheter coating
Poly(2-hydroxyethyl methacrylate)	coatings for vascular grafts and catheters
Polyethylene terephthalate	vascular grafts, shunts
Polysulfones	prosthetic heart valves; artificial heart structures
Polyetherurethanes	intra-aortic balloons, catheters, percutaneous leads
Polyetherurethane ureas	artificial heart components; heart valves; device coatings
Soft-tissue applications	
Low-density polyethylene	tubings; shunts; syringes
Polytetrafluoroethylene	facial prostheses
Polymethyl methacrylate	intraocular lenses
Polyamides	sutures
Poly(2-hydroxyethyl methacrylate)	controlled drug release; contact lenses; artificial organs
Polyethylene terephthalate	tissue patches
Polylactide coglycolide	bioresorbable sutures; controlled drug release
Polyorthoesters	controlled drug release
Polyanhydrides	controlled drug release
Polydimethylsiloxane	reconstructive devices; breast prostheses; shunts
Polyetherurethanes	wound dressing
Orthopedic/orthodontic applications	
High-density polyethylene	acetabular cups
Polymethyl methacrylate	dentures; bone cement; middle-ear prostheses
Extracorporeal applications	
Polypropylene (isotactic)	plasmapheresis membrane
Polytetrafluoroethylene	oxygenator membrane
Polyvinyl chloride	plasmapheresis membrane; blood bag
Polyacrylonitrile	hemodialysis membrane
Polydimethylsiloxane	oxygenator membrane

the high-strength acrylics used in orthopedics and dentistry. The properties of any material are governed by its chemical composition and by the intra- and intermolecular forces that dictate its molecular organization. Macromolecular structure in turn affects macroscopic properties and, ultimately, the interfacial behaviour of the material in contact with blood or host tissues.

Since the properties of each material are dependent on the chemical structure and macromolecular organization of its polymer chains, an understanding of some common structural features of various polymers provides considerable insight into their properties. Compared with complex biological molecules, synthetic polymers are relatively simple; often they comprise only one type of repeating subunit, analogous to a polypeptide consisting of just one repeating amino acid. On the basis of common structures and properties, synthetic polymers are classified into one of three categories: elastomers, which include natural and synthetic rubbers; thermoplastics; and thermosets. The properties that provide the basis for this classification include molecular weight, cross-link density, percent crystallinity, thermal transition temperature, and bulk mechanical properties.

Elastomers. Elastomers, which include rubber materials, have found wide use as biomaterials in cardiovascular and soft-tissue applications owing to their high elasticity, impact resistance, and gas permeability. Applications of elastomers include flexible tubing for pacemaker leads, vascular grafts, and catheters; biocompatible coatings and pumping diaphragms for artificial hearts and left-ventricular assist devices; grafts for reconstructive surgery and maxillofacial operations; wound dressings; breast prostheses; and membranes for implantable biosensors.

Elasticity, impact resistance, and gas permeability

Elastomers are typically amorphous with low cross-link density (although linear polyurethane block copolymers are an important exception). This gives them low to moderate modulus and tensile properties as well as high elasticity. For example, elastomeric devices can be extended by 100 to 1,000 percent of their initial dimensions without causing any permanent deformation to the material. Silicone rubbers such as Silastic (trademark), produced by the American manufacturer Dow Corning, Inc., are cross-linked, so that they cannot be melted or dissolved—although swelling may occur in the presence of a good solvent. Such properties contrast with those of the linear polyurethane elastomers, which consist of soft polyether amorphous segments and hard urethane-containing glassy or crystalline segments. The two segments are incompatible at room temperature and undergo microphase separation, forming hard domains dispersed in an amorphous matrix. A key feature of this macromolecular organization is that the hard domains serve as physical cross-links and reinforcing filler. This results in elastomeric materials that possess relatively high modulus and extraordinary long-term stability under sustained cyclic loading. In addition, they can be processed by methods common to thermoplastics.

Thermoplastics. Many common thermoplastics, such as polyethylene and polyester, are used as biomaterials. Thermoplastics usually exhibit moderate to high tensile strength (5 to 1,000 megapascals) with moderate elongation (2 to 100 percent), and they undergo plastic deformation at high strains. Thermoplastics consist of linear or branched polymer chains; consequently, most can undergo reversible melt-solid transformation on heating, which allows for relatively easy processing or reprocessing. Depending on the structure and molecular organization of the polymer chains, thermoplastics may be amorphous (*e.g.,* polystyrene), semicrystalline (*e.g.,* low-density polyethylene), or highly crystalline (*e.g.,* high-density polyethylene), or they may be processed into highly crystalline textile fibres (*e.g.,* polyester Dacron).

Some thermoplastic biomaterials, such as polylactic acid and polyglycolic acid, are polymers based on a repeating amino acid subunit. These polypeptides are biodegradable, and, along with biodegradable polyesters and polyorthoesters, they have applications in absorbable sutures and drug-release systems. The rate of biodegradation in the body can be adjusted by using copolymers. These are polymers that link two different monomer subunits into a single polymer chain. The resultant biomaterial exhibits properties, including biodegradation, that are intermediate between the two homopolymers.

Thermosets. Thermosetting polymers find only limited application in medicine, but their characteristic properties, which combine high strength and chemical resistance, are useful for some orthopedic and dental devices. Thermosetting polymers such as epoxies and acrylics are chemically inert, and they also have high modulus and tensile properties with negligible elongation (1 to 2 percent). The polymer chains in these materials are highly cross-linked and therefore have severely restricted macromolecular mobility; this limits extension of the polymer chains under an applied load. As a result, thermosets are strong but brittle materials.

Strength and chemical resistance

Cross-linking inhibits close packing of polymer chains, preventing formation of crystalline regions. Another consequence of extensive cross-linking is that thermosets do not undergo solid-melt transformation on heating, so that they cannot be melted or reprocessed.

APPLICATIONS OF BIOMATERIALS

Cardiovascular devices. Biomaterials are used in many blood-contacting devices. These include artificial heart valves, synthetic vascular grafts, ventricular assist devices, drug-release systems, extracorporeal systems, and a wide range of invasive treatment and diagnostic systems. An important issue in the design and selection of materials is the hemodynamic conditions in the vicinity of the device. For example, mechanical heart valve implants are intended for long-term use. Consequently, the hinge points of each valve leaflet and the materials must have excellent wear and fatigue resistance in order to open and close 80 times per minute for many years after implantation. In addition, the open valve must minimize disturbances to blood flow as blood passes from the left ventricle of the heart, through the heart valve, and into the ascending aorta of the arterial vascular system. To this end, the bileaflet valve disks of one type of implant are coated with pyrolytic carbon, which provides a relatively smooth, chemically inert surface. This is an important property, because surface roughness will cause turbulence in the blood flow, which in turn may lead to hemolysis of red cells, provide sites for adventitious bacterial adhesion and subsequent colonization, and, in areas of blood stasis, promote thrombosis and blood coagulation. The carbon-coated holding ring of this implant is covered with Dacron mesh fabric so that the surgeon can sew and fix the device to adjacent cardiac tissues. Furthermore, the porous structure of the Dacron mesh promotes tissue integration, which occurs over a period of weeks after implantation.

While the possibility of thrombosis can be minimized in blood-contacting biomaterials, it cannot be eliminated entirely. For this reason, patients who receive artificial heart valves or other blood-contacting devices also receive anticoagulation therapy. This is needed because all foreign surfaces initiate blood coagulation and platelet adhesion to some extent. Platelets are circulating cellular components of blood, two to four micrometres in size, that attach to foreign surfaces and actively participate in blood coagulation and thrombus formation. Research on new biomaterials for cardiovascular applications is largely devoted to understanding thrombus formation and to developing novel surfaces for biomaterials that will provide improved blood compatibility.

Vascular graft materials

Synthetic vascular graft materials are used to patch injured or diseased areas of arteries, for replacement of whole segments of larger arteries such as the aorta, and for use as sewing cuffs (as with the heart valve mentioned above). Such materials need to be flexible to allow for the difficulties of implantation and to avoid irritating adjacent tissues; also, the internal diameter of the graft should remain constant under a wide range of flexing and bending conditions, and the modulus or compliance of the vessel should be similar to that of the natural vessel. These aims are largely achieved by crimped woven Dacron and expanded polytetrafluoroethylene (ePTFE). Crimping of Dacron in processing results in a porous vascular graft that may be bent 180° or twisted without collapsing the internal diameter.

A biomaterial used for blood vessel replacement will be in contact not only with blood but also with adjacent soft tissues. Experience with different materials has shown that tissue growth into the interstices of the biomaterials aids healing and integration of the material with host tissue after implantation. In order for the tissue, which consists mostly of collagen, to grow in the graft, the vascular graft must have an open structure with pores at least 10 micrometres in diameter. These pores allow new blood capillaries that develop during healing to grow into the graft, and the blood then provides oxygen and other nutrients for fibroblasts and other cells to survive in the biomaterial matrix. Fibroblasts synthesize the structural protein tropocollagen, which is needed in the development of new fibrous tissue as part of the healing response to a surgical wound.

Occasionally, excessive tissue growth may be observed at the anastomosis, which is where the graft is sewn to the native artery. This is referred to as internal hyperplasia and is thought to result from differences in compliance between the graft and the host vessels. In addition, in order to optimize compatibility of the biomaterial with the blood, the synthetic graft eventually should be coated with a confluent layer of host endothelial cells, but this does not occur with current materials. Therefore, most proposed modifications to existing graft materials involve potential improvements in blood compatibility.

Artificial heart valves and vascular grafts, while not ideal, have been used successfully and have saved many thousands of lives. However, the risk of thrombosis has limited the success of existing cardiovascular devices and has restricted potential application of the biomaterials to other devices. For example, there is an urgent clinical need for blood-compatible, synthetic vascular grafts of small diameter in peripheral vascular surgery—*e.g.*, in the legs—but this is currently impracticable with existing biomaterials because of the high risk of thrombotic occlusion. Similarly, progress with implantable miniature sensors, designed to measure a wide range of blood conditions continuously, has been impeded because of problems directly attributable to the failure of existing biomaterials. With such biocompatibility problems resolved, biomedical sensors would provide a very important contribution to medical diagnosis and monitoring. Considerable advances have been made in the ability to manipulate molecular architecture at the surfaces of materials by using chemisorbed or physisorbed monolayer films. Such progress in surface modification, combined with the development of nanoscale probes that permit examination at the molecular and submolecular level, provide a strong basis for optimism in the development of specialty biomaterials with improved blood compatibility.

The need for improved blood compatibility

Orthopedic devices. Joint replacements, particularly at the hip, and bone fixation devices have become very successful applications of materials in medicine. The use of pins, plates, and screws for bone fixation to aid recovery of bone fractures has become routine, with the number of annual procedures approaching five million in the United States alone. In joint replacement, typical patients are age 55 or older and suffer from debilitating rheumatoid arthritis, osteoarthritis, or osteoporosis. Orthopedic surgeries for artificial joints exceed 1.5 million each year, with actual joint replacement accounting for about half of the procedures. A major focus of research is the development of new biomaterials for artificial joints intended for younger, more active patients.

Hip-joint replacements are principally used for structural support. Consequently, they are dominated by materials that possess high strength, such as metals, tough plastics, and reinforced polymer-matrix composites. In addition, biomaterials used for orthopedic applications must have high modulus, long-term dimensional stability, high fatigue resistance, long-term biostability, excellent abrasion resistance, and biocompatibility (*i.e.*, there should be no adverse tissue response to the implanted device). Early developments in this field used readily available materials such as stainless steels, but evidence of corrosion after implantation led to their replacement by more stable materials, particularly titanium alloys, cobalt-chromium-molybdenum alloys, and carbon fibre-reinforced polymer composites. A typical modern artificial hip consists of a nitrided and highly polished cobalt-chromium ball connected to a titanium alloy stem that is inserted into the femur and cemented into place by in situ polymerization of polymethylmethacrylate. The articulating component of the joint consists of an acetabular cup made of tough, creep-resistant, ultrahigh-molecular-weight polyethylene. Abrasion at the ball-and-cup interface can lead to the production of wear particles, which in turn can lead to significant inflammatory reaction by the host. Consequently, much research on the development of hip-joint materials has been devoted to optimizing the properties of the articulating components in order to eliminate surface wear. Other modifications include porous coatings made by sintering the metal surface or coatings of wire mesh or hydroxyapatite; these promote bone growth and integration between the implant and the host, eliminating the need for an acrylic bone cement.

The artificial hip

While the strength of the biomaterials is important, an-

other goal is to match the mechanical properties of the implant materials with those of the bone in order to provide a uniform distribution of stresses (load sharing). If a bone is loaded insufficiently, the stress distribution will be made asymmetric, and this will lead to adaptive remodeling with cortical thinning and increased porosity of the bone. Such lessons in structure hierarchy and in the structure-property relationships of materials have been obtained from studies on biologic composite materials, and they are being translated into new classes of synthetic biomaterials. One development is carbon fibre-reinforced polymer-matrix composites. Typical matrix polymers include polysulfone and polyetheretherketones. The strength of these composites is lower than that of metals, but it more closely approximates that of bone. (R.E.M.)

BIBLIOGRAPHY

General works. Overviews of the properties and production of all engineering materials can be found in the following texts: JAMES F. SHACKELFORD, *Introduction to Materials Science for Engineers*, 3rd ed. (1992); WILLIAM D. CALLISTER, JR., *Materials Science and Engineering: An Introduction*, 2nd ed. (1991); RICHARD A. FLINN and PAUL K. TROJAN, *Engineering Materials and Their Applications*, 4th ed. (1990); DONALD R. ASKELAND, *The Science and Engineering of Materials*, 2nd ed. (1989); and MICHAEL F. ASHBY and DAVID R.H. JONES, *Engineering Materials: An Introduction to Their Properties and Applications* (1980), readable even for those with no previous materials science background and providing clearly described examples of innovative ways to use materials. *Materials Science and Engineering for the 1990s* (1989) comprehensively describes new directions to be taken in materials science; it is written in a readily comprehensible manner by members of committees of the National Research Council (U.S.). An entire issue of *Advanced Materials & Processes*, vol. 141, no. 1 (January 1992), is devoted to a forecast of developments in various materials, trends in materials processing, and advances in testing and characterization of materials. MICHAEL B. BEVER (ed.), *Encyclopedia of Materials Science and Engineering*, 8 vol. (1986), with supplementary vols., is a comprehensive reference work.

Materials for energy. Three journal articles on the topic are RICHARD S. CLAASEN and LOUIS A. GIRIFALCO, "Materials for Energy Utilization," *Scientific American*, 255(4):102–104, 109–112, 117 (October 1986); RICHARD S. CLAASEN, "Materials for Advanced Energy Technologies," *Science*, 191(4227):739–745 (Feb. 20, 1976); and BERNARD L. COHEN, "The Disposal of Radioactive Wastes from Fission Reactors," *Scientific American*, 236(6):21–31 (June 1977).

Materials for ground transportation. A lucid account of the shift away from conventional steels in modern automobiles is found in the excellent introductory article by W. DALE COMPTON and NORMAN A. GJOSTEIN, "Materials for Ground Transportation," *Scientific American*, 255(4):92–100 (October 1986). KAREN WRIGHT, "The Shape of Things to Go," *Scientific American*, 262(5):92–101 (May 1990), projects the effect of advanced technology on automobiles of the future.

Materials for aerospace. An overview is found in MORRIS A. STEINBERG, "Materials for Aerospace," *Scientific American*, 255(4):66–72 (October 1986). An entire issue of *Advanced Materials & Processes*, vol. 137, no. 4 (April 1990), is devoted to aerospace materials and applications. A special section on frontiers in materials science in *Science*, 255(5048):1077–1112 (Feb. 28, 1992), discusses polymers and aircraft engine materials, among other subjects.

Works on composites include TSU-WEI CHOU, ROY L. MCCULLOUGH, and R. BYRON PIPES, "Composites," *Scientific American*, 255(4):192–203 (October 1986); ROY L. MCCULLOUGH, *Concepts of Fiber-Resin Composites* (1971); STEPHEN W. TSAI and H. THOMAS HAHN, *Introduction to Composite Materials* (1980); and JACK R. VINSON and TSU-WEI CHOU, *Composite Materials and Their Use in Structures* (1975).

Materials for communications. A useful introduction is by JOHN S. MAYO, "Materials for Information and Communication," *Scientific American*, 255(4):58–66 (October 1986). Discussions of electronic and photonic materials may be found in the following essays, all from *AT&T Technical Journal:* in vol. 69, no. 6 (November/December 1990), see C. KUMAR N. PATEL, "Materials and Processing: Core Competencies and Strategic Resources," pp. 2–8; KENNETH E. BENSON, LIONEL C. KIMERLING, and PETER T. PANOUSIS, "Reaching the Limits in Silicon Processing," pp. 16–31; ELSA REICHMANIS and LARRY F. THOMPSON, "Challenges in Lithographic Materials and Processes," pp. 32–45; and JAMES W. MITCHELL, JORGE LUIS VALDES, and GARDY CADET, "Benign Precursors for Semiconductor Processing," pp. 101–112; in vol. 68, no. 1 (January/February 1989), see JIM E. CLEMANS *et al.*, "Bulk III-V Compound Semiconductor Crystal Growth," pp. 29–42; and W. DEXTER JOHNSTON, JR., MICHAEL A. DIGUISEPPE, and DANIEL P. WILT, "Liquid and Vapor Phase Growth of III-V Materials for Photonic Devices," pp. 53–63; and in vol. 71, no. 1 (January/February 1992), see JOHN L. ZYSKIND *et al.*, "Erbium-Doped Fiber Amplifiers and the Next Generation of Lightwave Systems," pp. 53–62 .

Materials for medicine. ROBERT A. FULLER and JONATHAN J. ROSEN, "Materials for Medicine," *Scientific American*, 255(4):118–125 (October 1986), offers an overview of the subject. S.A. BARENBERG, "Abridged Report of the Committee to Survey the Needs and Opportunities for the Biomaterials Industry," *Journal of Biomedical Materials Research*, 22(12):1267–92 (December 1988), surveys the applications of materials in medicine and highlights projected areas of clinical need. JOON BU PARK, *Biomaterials Science and Engineering* (1984), provides a qualitative university-level introduction to the field of biomaterials. MICHAEL SZYCHER (ed.), *Biocompatible Polymers, Metals, and Composites* (1983), is a collection of detailed review articles that covers materials in medicine and biocompatibility and contains a pragmatic assessment of clinical and commercial aspects, including how to sterilize and package biomaterials. HARRY R. ALLCOCK and FREDERICK W. LAMPE, *Contemporary Polymer Chemistry*, 2nd ed. (1990), is a basic textbook of polymer science, providing a university-level introduction to synthesis and characterization of polymers, including biomedical polymers. Advanced biomaterials texts with emphasis on research include MICHAEL SZYCHER (ed.), *High Performance Biomaterials: A Comprehensive Guide to Medical and Pharmaceutical Applications* (1991), research articles covering orthopedic and cardiovascular biomaterials as well as most other areas of materials in medicine; JOSEPH D. ANDRADE (ed.), *Surface and Interfacial Aspects of Biomedical Polymers*, vol. 1, *Surface Chemistry and Physics* (1985), articles on surface characterization methods applied to biomaterials, including a quantitative presentation of the interactions of blood components (especially proteins) with biomaterial surfaces; HOWARD P. GREISLER, *New Biologic and Synthetic Vascular Prostheses* (1991), a biological perspective on blood interactions, wound healing, and tissue integration with biomaterials and surface modified materials; D.F. WILLIAMS, *Blood Compatibility*, 2 vol. (1987), detailed review articles covering blood interactions with biomaterials and prosthetic devices and methods of modifying the surface of biomaterials; and IL.L. GOLDSMITH and V.T. TURITTO, "Rheological Aspects of Thrombosis and Hemostasis: Basic Principles and Applications," *Thrombosis and Haemostasis*, 55(3):415–435 (1986), a detailed and quantitative review article that describes and models blood flow and rheology in the vascular system, including the effects of different blood components.

The Foundations of Mathematics

The study of the foundations of mathematics is the examination of the underlying assumptions and procedures of mathematics, and its limitations. Because mathematics has served as a model for rational inquiry in the West and is used extensively in the sciences, foundational studies have far-reaching consequences for the reliability and extensibility of rational thought itself.

For 2,000 years the foundations of mathematics seemed perfectly solid. Euclid's *Elements* (*c.* 300 BC), which presented a set of formal logical arguments based on a few basic terms and axioms, provided a systematic method of rational exploration that guided mathematicians, philosophers, and scientists well into the 19th century. Even serious objections to the lack of rigour in Sir Isaac Newton's notion of fluxions (derivatives) in the calculus, raised by the Anglo-Irish empiricist George Berkeley (among others), did not call into question the basic foundations of mathematics. The discovery in the 19th century of consistent alternative geometries, however, precipitated a crisis, for it showed that Euclidean geometry, based on seemingly the most intuitively obvious axiomatic assumptions, did not correspond with reality as mathematicians had believed. This, together with the bold discoveries of the German mathematician Georg Cantor in set theory, made it clear that, to avoid further confusion and satisfactorily answer paradoxical results, a new and more rigorous foundation for mathematics was necessary.

Thus began the 20th-century quest to rebuild mathematics on a new basis independent of geometric intuitions. Early efforts included those of the logicist school of the British mathematicians Bertrand Russell and Alfred North Whitehead, the formalist school of the German mathematician David Hilbert, the intuitionist school of the Dutch mathematician L.E.J. Brouwer, and the French set theory school of mathematicians collectively writing under the pseudonym of Nicolas Bourbaki. Some of the most promising current research is based on the development of category theory by the American mathematician Saunders Mac Lane and the Polish-born American mathematician Samuel Eilenberg following World War II.

This article presents the historical background of foundational questions and 20th-century efforts to construct a new foundational basis for mathematics.

This article is divided into the following sections:

Ancient Greece to the Enlightenment

A remarkable amount of practical mathematics, some of it even fairly sophisticated, was already developed as early as 2000 BC by the agricultural civilizations of Egypt and Mesopotamia, and perhaps even farther east. However, the first to exhibit an interest in the foundations of mathematics were the ancient Greeks.

Arithmetic or geometry. Early Greek philosophy was dominated by a dispute as to which is more basic, arithmetic or geometry, and thus whether mathematics should be concerned primarily with the (positive) integers or the (positive) reals, the latter then being conceived as ratios of geometric quantities. (The Greeks confined themselves to positive numbers, as negative numbers were introduced only much later in India by Brahmagupta.) Underlying this dispute was a perceived basic dichotomy, not confined to mathematics but pervading all nature: is the universe made up of discrete atoms (as the philosopher Democritus believed) which hence can be counted, or does it consist of one or more continuous substances (as Thales of Miletus is reputed to have believed) and thus can only be measured? This dichotomy was presumably inspired by a linguistic distinction, analogous to that between English count nouns, such as "apple," and mass nouns, such as "water." As Aristotle later pointed out, in an effort to mediate between these divergent positions, water can be measured by counting cups.

Discrete atoms versus continuous substances

The Pythagorean school of mathematics, founded on the doctrines of the Greek philosopher Pythagoras, originally insisted that only natural and rational numbers exist. Its members only reluctantly accepted the discovery that $\sqrt{2}$, the ratio of the diagonal of a square to its side, could not be expressed as the ratio of whole numbers. The remarkable proof of this fact has been preserved by Aristotle. (See ANALYSIS: *Real analysis.*)

The contradiction between rationals and reals was finally resolved by Eudoxus of Cnidus, a disciple of Plato, who pointed out that two ratios of geometric quantities are equal if and only if they partition the set of (positive) rationals in the same way, thus anticipating the German mathematician Richard Dedekind (1831–1916), who defined real numbers as such partitions.

Being versus becoming. Another dispute among pre-Socratic philosophers was more concerned with the physical world. Parmenides claimed that in the real world there is no such thing as change and that the flow of time is an illusion, a view with parallels in the Einstein-Minkowski four-dimensional space-time model of the universe. Heracleitus, on the other hand, asserted that change is all-pervasive and is reputed to have said that one cannot step into the same river twice.

Zeno of Elea, a follower of Parmenides, claimed that change is actually impossible and produced four paradoxes to show this. The most famous of these describes a race between Achilles and a tortoise. Since Achilles can run much faster than the tortoise, let us say twice as fast, the latter is allowed a head start of one mile. When Achilles

has run one mile, the tortoise will have run half as far again—that is, half a mile. When Achilles has covered that additional half-mile, the tortoise will have run a further quarter-mile. After $n + 1$ stages, Achilles has run

$$1 + \frac{1}{2} + \cdots + \frac{1}{2^n} = 2 - \frac{1}{2^n}$$

miles and the tortoise has run

$$1 + \frac{1}{2} + \cdots + \frac{1}{2^n} + \frac{1}{2^{n+1}}$$

miles, being still $1/2^{n+1}$ miles ahead. So how can Achilles ever catch up with the tortoise (Figure 1)?

Zeno's paradoxes may also be interpreted as showing that space and time are not made up of discrete atoms but are substances which are infinitely divisible. Mathematically speaking, his argument involves the sum of the infinite geometric progression

Infinite geometric progression

$$1 + \frac{1}{2} + \frac{1}{4} + \cdots,$$

no finite partial sum of which adds up to 2. As Aristotle would later say, this progression is only potentially infinite. It is now understood that Zeno was trying to come to grips with the notion of limit, which was not formally explained until the 19th century, although a start in that direction had been made by the French encyclopaedist Jean Le Rond d'Alembert (1717–83).

Universals. The Athenian philosopher Plato believed that mathematical entities are not just human inventions but have a real existence. For instance, according to Plato, the number 2 is an ideal object. This is sometimes called an "idea," from the Greek *eide,* or "universal," from the Latin *universalis,* meaning "that which pertains to all." But Plato did not have in mind a "mental image," as "idea" is usually used. The number 2 is to be distinguished from a collection of two stones or two apples or, for that matter, two platinum balls in Paris.

What, then, are these Platonic ideas? Already in ancient Alexandria some people speculated that they are words. This is why the Greek word *logos,* originally meaning "word," later acquired a theological meaning as denoting the ultimate reality behind the "thing." An intense debate occurred in the Middle Ages over the ontological status of universals. Three dominant views prevailed: realism, from the Latin *res* ("thing"), which asserts that universals have an extra-mental reality—that is, they exist independently of perception; conceptualism, which asserts that universals exist as entities within the mind but have no extra-mental existence; and nominalism, from the Latin *nomen* ("name"), which asserts that universals exist neither in the mind nor in the extra-mental realm but are merely names that refer to collections of individual objects.

It would seem that Plato believed in a notion of truth independent of the human mind. In the *Meno* Plato's teacher Socrates asserts that it is possible to come to know this truth by a process akin to memory retrieval. Thus, by clever questioning, Socrates managed to bring an uneducated person to "remember," or rather to reconstruct, the proof of a mathematical theorem.

The axiomatic method. Perhaps the most important contribution to the foundations of mathematics made by the ancient Greeks was the axiomatic method and the notion of proof. This was insisted upon in Plato's Academy and reached its high point in Alexandria about 300 BC with Euclid's *Elements*. This notion survives today, except for some cosmetic changes.

Euclid's *Elements*

The idea is this: there are a number of basic mathematical truths, called axioms or postulates, from which other true statements may be derived in a finite number of steps. It may take considerable ingenuity to discover a proof; but it is now held that it must be possible to check mechanically, step by step, whether a purported proof is indeed correct, and nowadays a computer should be able to do this. The mathematical statements that can be proved are called theorems, and it follows that, in principle, a mechanical device, such as a modern computer, can generate all theorems.

Two questions about the axiomatic method were left unanswered by the ancients: are all mathematical truths axioms or theorems (this is referred to as completeness), and can it be determined mechanically whether a given statement is a theorem (this is called decidability)? These questions were raised implicitly by David Hilbert (1862–1943) about 1900 and were resolved later in the negative, completeness by the Austrian-American logician Kurt Gödel (1906–78) and decidability by the American logician Alonzo Church (1903–95).

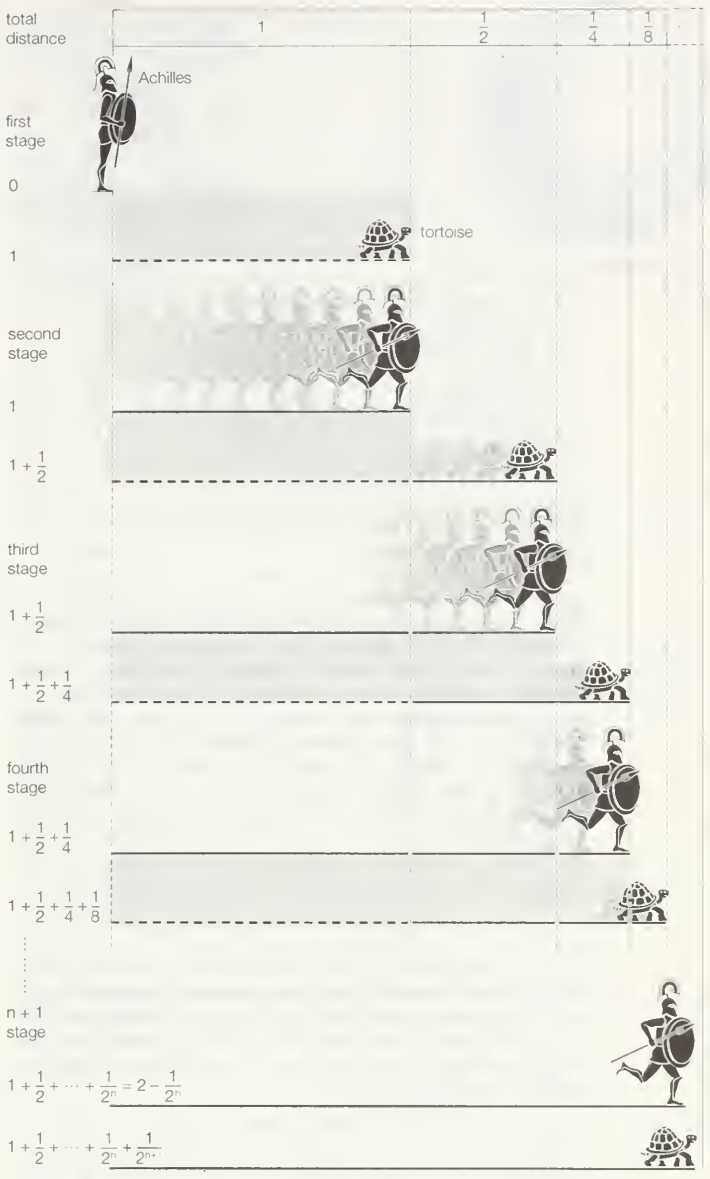

Figure 1: Zeno's paradox, illustrated by Achilles racing a tortoise.

Encyclopædia Britannica, Inc.

Euclid's work dealt with number theory and geometry, essentially all the mathematics then known. Since the middle of the 20th century a gradually changing group of mostly French mathematicians under the pseudonym Nicolas Bourbaki has tried to emulate Euclid in writing a new *Elements of Mathematics* based on their theory of structures. Unfortunately, they just missed out on the new ideas from category theory.

Number systems. While the ancient Greeks were familiar with the positive integers, rationals, and reals, zero (used as an actual number instead of denoting a missing number) and the negative numbers were first used in India, as far as is known, by Brahmagupta in the 7th century AD. Complex numbers were introduced by the Italian Renaissance mathematician and physician Gerolamo Cardano (1501–76), not just to solve equations such as $x^2 + 1 = 0$ but because they were needed to find real solutions of certain cubic equations with real coefficients.

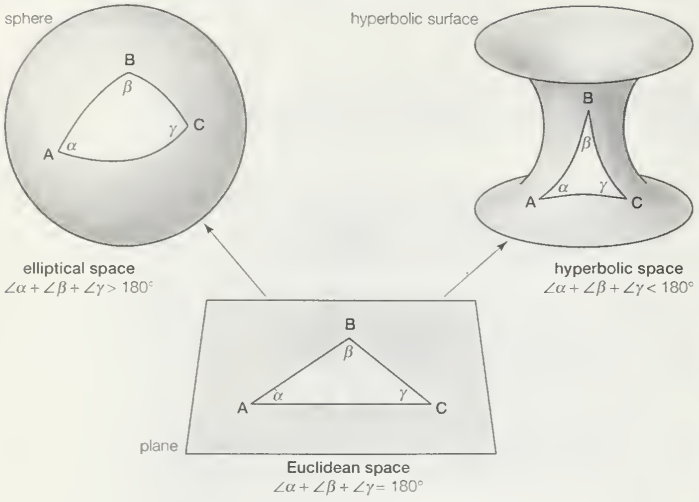

Figure 2: Contrasting triangles in Euclidean, elliptic, and hyperbolic spaces.
Encyclopædia Britannica, Inc

Much later, the German mathematician Carl Friedrich Gauss (1777–1855) proved the fundamental theorem of algebra, that all equations with complex coefficients have complex solutions, thus removing the principal motivation for introducing new numbers. Still, the Irish mathematician Sir William Rowan Hamilton (1805–65) and the French mathematician Olinde Rodrigues (1794–1851) invented quaternions in the mid-19th century, but these proved to be less popular in the scientific community until quite recently.

Currently, a logical presentation of the number system, as taught at the university level, would be as follows:

$$\mathbf{N} \rightarrow \mathbf{Z} \rightarrow \mathbf{Q} \rightarrow \mathbf{R} \rightarrow \mathbf{C} \rightarrow \mathbf{H}.$$

Here the boldfaced letters, introduced by Nicolas Bourbaki, refer to the natural numbers, integers, rationals, reals, complex numbers, and quaternions, respectively, and the arrows indicate inclusion of each number system into the next. However, as has been shown, the historical development proceeds differently:

$$\mathbf{N}^+ \rightarrow \mathbf{Q}^+ \rightarrow \mathbf{R}^+ \rightarrow \mathbf{R} \rightarrow \mathbf{C} \rightarrow \mathbf{H},$$

where the plus sign indicates restriction to positive elements. This is the development, up to **R**, which is often adhered to at the high-school level.

The reexamination of infinity

Calculus reopens foundational questions. Although mathematics flourished after the end of the Classical Greek period for 800 years in Alexandria and, after an interlude in India and the Islāmic world, again in Renaissance Europe, philosophical questions concerning the foundations of mathematics were not raised until the invention of calculus and then not by mathematicians but by the philosopher George Berkeley (1685–1753).

Sir Isaac Newton in England and Gottfried Wilhelm Leibniz in Germany had independently developed the calculus on a basis of heuristic rules and methods markedly deficient in logical justification. As is the case in many new developments, utility outweighed rigour, and, though Newton's fluxions (or derivatives) and Leibniz's infinitesimals (or differentials) lacked a coherent rational explanation, their power in answering heretofore unanswerable questions was undeniable. Unlike Newton, who made little effort to explain and justify fluxions, Leibniz, as an eminent and highly regarded philosopher, was influential in propagating the idea of infinitesimals, which he described as infinitely small actual numbers—that is, less than $1/n$ in absolute value for each positive integer n and yet not equal to zero. Berkeley, concerned over the deterministic and atheistic implications of philosophical mechanism, set out to reveal contradictions in the calculus in his influential book *The Analyst; or, A Discourse Addressed to an Infidel Mathematician.* There he scathingly wrote about these fluxions and infinitesimals, "They are neither finite quantities, nor quantities infinitely small, nor yet nothing. May we not call them the ghosts of departed quantities?" and further asked, "Whether mathematicians, who are so delicate in religious points, are strictly scrupulous in their own science? Whether they do not submit to authority, take things upon trust, and believe points inconceivable?"

Infinitesimals

Berkeley's criticism was not fully met until the 19th century, when it was realized that, in the expression dy/dx, dx and dy need not lead an independent existence. Rather, this expression could be defined as the limit of ordinary ratios $\Delta y/\Delta x$, as Δx approaches zero without ever being zero. Moreover, the notion of limit was then explained quite rigorously, in answer to such thinkers as Zeno and Berkeley. (See ANALYSIS: *Real analysis.*)

It was not until the middle of the 20th century that the logician Abraham Robinson (1918–74) showed that the notion of infinitesimal was in fact logically consistent and that, therefore, infinitesimals could be introduced as new kinds of numbers. This led to a novel way of presenting the calculus, called nonstandard analysis, which has, however, not become as widespread and influential as it might have.

Nonstandard analysis

Robinson's argument was this: if the assumptions behind the existence of an infinitesimal ξ led to a contradiction, then this contradiction must already be obtainable from a finite set of these assumptions, say from:

$$0 < \xi, \xi < 1, \xi < \frac{1}{2}, \cdots, \xi < \frac{1}{n}.$$

But this finite set is consistent, as is seen by taking $\xi = 1/(n+1)$.

Non-Euclidean geometries. When Euclid presented his axiomatic treatment of geometry, one of his assumptions, his fifth postulate, appeared to be less obvious or fundamental than the others. As it is now conventionally formulated, it asserts that there is exactly one parallel to a given line through a given point. Attempts to derive this from Euclid's other axioms did not succeed, and, at the beginning of the 19th century, it was realized that Euclid's fifth postulate is, in fact, independent of the others. It was then seen that Euclid had described not the one true geometry but only one of a number of possible geometries.

Euclid's parallel postulate

Elliptic and hyperbolic geometries. Within the framework of Euclid's other four postulates (and a few that he omitted), there were also possible elliptic and hyperbolic geometries. In plane elliptic geometry there are no parallels to a given line through a given point; it may be viewed as the geometry of a spherical surface on which antipodal points have been identified and all lines are great circles. This was not viewed as revolutionary. More exciting was plane hyperbolic geometry, developed independently by the Hungarian mathematician János Bolyai (1802–60) and the Russian mathematician Nikolay Lobachevsky (1792–1856), in which there is more than one parallel to a given line through a given point. This geometry is more difficult to visualize, but a helpful model presents the hyperbolic plane as the interior of a circle, in which straight lines take the form of arcs of circles perpendicular to the circumference.

Another way to distinguish the three geometries is to look at the sum of the angles of a triangle. It is 180° in Euclidean geometry, as first reputedly discovered by Thales of Miletus (fl. 6th century BC), whereas it is more than 180° in elliptic and less than 180° in hyperbolic geometry. See Figure 2.

Riemannian geometry. The discovery that there is more than one geometry was of foundational significance and contradicted the German philosopher Immanuel Kant (1724–1804). Kant had argued that there is only one true geometry, Euclidean, which is known to be true a priori by an inner faculty (or intuition) of the mind. For Kant, and practically all other philosophers and mathematicians of his time, this belief in the unassailable truth of Euclidean geometry formed the foundation and justification for further explorations into the nature of reality. With the discovery of consistent non-Euclidean geometries, there was a subsequent loss of certainty and trust in this innate

intuition, and this was fundamental in separating mathematics from a rigid adherence to an external sensory order (no longer vouchsafed as "true") and led to the growing abstraction of mathematics as a self-contained universe. This divorce from geometric intuition added impetus to later efforts to rebuild assurance of truth on the basis of logic.

What then is the correct geometry for describing the space (actually space-time) we live in? It turns out to be none of the above, but a more general kind of geometry, as was first discovered by the German mathematician Bernhard Riemann (1826–66). In the early 20th century, Albert Einstein showed, in the context of his general theory of relativity, that the true geometry of space is only approximately Euclidean. It is a form of Riemannian geometry in which space and time are linked in a four-dimensional manifold, and it is the curvature at each point that is responsible for the gravitational "force" at that point. Einstein spent the last part of his life trying to extend this idea to the electromagnetic force, hoping to reduce all physics to geometry, but a successful unified field theory eluded him.

Einstein's space-time manifold

Cantor. In the 19th century, the German mathematician Georg Cantor (1845–1918) returned once more to the notion of infinity and showed that, surprisingly, there is not just one kind of infinity but many kinds. In particular, while the set **N** of natural numbers and the set of all subsets of **N** are both infinite, the latter collection is more numerous, in a way that Cantor made precise, than the former. He proved that **N**, **Z**, and **Q** all have the same size, since it is possible to put them into one-to-one correspondence with one another, but that **R** is bigger, having the same size as the set of all subsets of **N**.

Continuum hypothesis

However, Cantor was unable to prove the so-called continuum hypothesis, which asserts that there is no set that is larger than **N** yet smaller than the set of its subsets. It was shown only in the 20th century, by Gödel and the American logician Paul Cohen (b. 1934), that the continuum hypothesis can be neither proved nor disproved from the usual axioms of set theory. Cantor had his detractors, most notably the German mathematician Leopold Kronecker (1823–91), who felt that Cantor's theory was too metaphysical and that his methods were not sufficiently constructive (see below *The quest for rigour: Formal foundations: Nonconstructive arguments*).

The quest for rigour

FORMAL FOUNDATIONS

Set theoretic beginnings. While laying rigorous foundations for mathematics, 19th-century mathematicians discovered that the language of mathematics could be reduced to that of set theory (developed by Cantor), dealing with membership ($\in$) and equality ($=$), together with some rudimentary arithmetic, containing at least symbols for zero (0) and successor (S). Underlying all this were the basic logical concepts: conjunction ($\wedge$), disjunction ($\vee$), implication ($\supset$), negation ($\neg$), and the universal ($\forall$) and existential ($\exists$) quantifiers (formalized by the German mathematician Gottlob Frege [1848–1925]). (The modern notation owes more to the influence of the English logician Bertrand Russell [1872–1970] and the Italian mathematician Giuseppe Peano [1858–1932] than to that of Frege.) For an extensive discussion of logic symbols and operations, see LOGIC: *Logic systems: Formal logic.*

For some time, logicians were obsessed with a principle of parsimony, called Ockham's razor, which justified them in reducing the number of these fundamental concepts, for example, by defining $p \supset q$ (read p implies q) as $\neg p \vee q$ or even as $\neg(p \wedge \neg q)$. While this definition, even if unnecessarily cumbersome, is legitimate classically, it is not permitted in intuitionistic logic (see below *Intuitionistic logic*). In the same spirit, many mathematicians adopted the Wiener-Kuratowski definition of the ordered pair $<a,b>$ as $\{\{a\}, \{a,b\}\}$, where $\{a\}$ is the set whose sole element is a, which disguises its true significance.

Logic had been studied by the ancients, in particular by Aristotle and the Stoic philosophers. Philo of Megara (fl. *c.* 250 BC) had observed (or postulated) that $p \supset q$ is false if and only if p is true and q is false. Yet the intimate connection between logic and mathematics had to await the insight of 19th-century thinkers, in particular Frege.

Frege was able to explain most mathematical notions with the help of his comprehension scheme, which asserts that, for every φ (formula or statement), there should exist a set X such that, for all x, $x \in X$ if and only if $\varphi(x)$ is true. Moreover, by the axiom of extensionality, this set X is uniquely determined by $\varphi(x)$. A flaw in Frege's system was uncovered by Russell, who pointed out some obvious contradictions involving sets that contain themselves as elements—*e.g.*, by taking $\varphi(x)$ to be $\neg(x \in x)$. Russell illustrated this by what has come to be known as the barber paradox: A barber states that he shaves all who do not shave themselves. Who shaves the barber? Any answer contradicts the barber's statement. To avoid these contradictions Russell introduced the concept of types, a hierarchy (not necessarily linear) of elements and sets such that definitions always proceed from more basic elements (sets) to more inclusive sets, hoping that self-referencing and circular definitions would then be excluded. With this type distinction, $x \in X$ only if X is of an appropriate higher type than x.

The type theory proposed by Russell, later developed in collaboration with the English mathematician Alfred North Whitehead (1861–1947) in their monumental *Principia Mathematica* (1910–13), turned out to be too cumbersome to appeal to mathematicians and logicians, who managed to avoid Russell's paradox in other ways. Mathematicians made use of the Neumann-Gödel-Bernays set theory, which distinguishes between small sets and large classes, while logicians preferred an essentially equivalent first-order language, the Zermelo-Fraenkel axioms, which allow one to construct new sets only as subsets of given old sets. Mention should also be made of the system of the American philosopher Willard Van Orman Quine (b. 1908), which admits a universal set. (Cantor had not allowed such a "biggest" set, as the set of all its subsets would have to be still bigger.) Although type theory was greatly simplified by Alonzo Church and the American mathematician Leon Henkin (b. 1921), it came into its own only with the advent of category theory (see below *Category theory*).

Principia Mathematica

Foundational logic. The prominence of logic in foundations led some people, referred to as logicists, to suggest that mathematics is a branch of logic. The concepts of membership and equality could reasonably be incorporated into logic, but what about the natural numbers? Kronecker had suggested that, while everything else was made by man, the natural numbers were given by God. The logicists, however, believed that the natural numbers were also man-made, inasmuch as definitions may be said to be of human origin.

Russell proposed that the number 2 be defined as the set of all two-element sets, that is, $X \in 2$ if and only if X has distinct elements x and y and every element of X is either x or y. The Hungarian-born American mathematician John von Neumann (1903–57) suggested an even simpler definition, namely that $X \in 2$ if and only if $X = 0$ or $X = 1$, where 0 is the empty set and 1 is the set consisting of 0 alone. Both definitions require an extralogical axiom to make them work—the axiom of infinity, which postulates the existence of an infinite set. Since the simplest infinite set is the set of natural numbers, one cannot really say that arithmetic has been reduced to logic. Most mathematicians follow Peano, who preferred to introduce the natural numbers directly by postulating the crucial properties of 0 and the successor operation S, among which one finds the principle of mathematical induction.

The logicist program might conceivably be saved by a 20th-century construction usually ascribed to Church, though he had been anticipated by the Austrian philosopher Ludwig Wittgenstein (1889–1951). According to Church, the number 2 is the process of iteration; that is, 2 is the function which to every function f assigns its iterate $2(f) = f\ f$, where $(f\ f)(x) = f(f(x))$. There are some type-theoretical difficulties with this construction, but these can be overcome if quantification over types is allowed; this is finding favour in theoretical computer science.

Impredicative constructions. A number of 19th-century mathematicians found fault with the program of reducing mathematics to arithmetic and set theory as suggested by the work of Cantor and Frege. In particular, the French mathematician Henri Poincaré (1854–1912) objected to impredicative constructions, which construct an entity of a certain type in terms of entities of the same or higher type—*i.e.*, self-referencing constructions and definitions. For example, when proving that every bounded nonempty set X of real numbers has a least upper bound a, one proceeds as follows. (For this purpose, it will be convenient to think of a real number, following Dedekind, as a set of rationals that contains all the rationals less than any element of the set.) One lets $x \in a$ if and only if $x \in y$ for some $y \in X$; but here y is of the same type as a.

Least upper bound

It would seem that to do ordinary analysis one requires impredicative constructions. Russell and Whitehead tried unsuccessfully to base mathematics on a predicative type theory; but, though reluctant, they had to introduce an additional axiom, the axiom of reducibility, which rendered their enterprise impredicative after all. More recently, the Swedish logician Per Martin-Löf presented a new predicative type theory, but no one claims that this is adequate for all of classical analysis. However, the German-American mathematician Hermann Weyl (1885–1955) and the American mathematician Solomon Feferman have shown that impredicative arguments such as the above can often be circumvented and are not needed for most, if not all, of analysis. On the other hand, as was pointed out by the Italian computer scientist Giuseppe Longo (b. 1929), impredicative constructions are extremely useful in computer science—namely, for producing fixpoints (entities that remain unchanged under a given process).

Nonconstructive arguments. Another criticism of the Cantor-Frege program was raised by Kronecker, who objected to nonconstructive arguments, such as the following proof that there exist irrational numbers a and b such that a^b is rational. If $\sqrt{2}^{\sqrt{2}}$ is rational, then the proof is complete; otherwise take $a = \sqrt{2}^{\sqrt{2}}$ and $b = \sqrt{2}$, so that $a^b = 2$. The argument is nonconstructive, because it does not tell us which alternative holds, even though more powerful mathematics will, as was shown by the Russian mathematician Aleksandr Osipovich Gelfond (1906–68). In the present case, the result can be proved constructively by taking $a = \sqrt{2}$ and $b = 2\log_2 3$. But there are other classical theorems for which no constructive proof exists.

Consider, for example, the statement

$$\exists_x(\exists_y \varphi(y) \supset \varphi(x)),$$

which symbolizes the statement that there exists a person who is famous if there are any famous people. This can be proved with the help of De Morgan's laws, named after the English mathematician and logician Augustus De Morgan (1806–71). It asserts the equivalence of $\exists_y \varphi(y)$ with $\neg\forall_y \neg\varphi(y)$, using classical logic, but there is no way one can construct such an x, for example, when $\varphi(x)$ asserts the existence of a well-ordering of the reals, as was proved by Feferman. An ordered set is said to be well-ordered if every nonempty subset has a least element. It had been shown by the German mathematician Ernst Zermelo (1871–1951) that every set can be well-ordered, provided one adopts another axiom, the axiom of choice, which says that, for every nonempty family of nonempty sets, there is a set obtainable by picking out exactly one element from each of these sets. This axiom is a fertile source of nonconstructive arguments.

Well-ordered sets and the axiom of choice

Intuitionistic logic. The Dutch mathematician L.E.J. Brouwer (1881–1966) in the early 20th century had the fundamental insight that such nonconstructive arguments will be avoided if one abandons a principle of classical logic which lies behind De Morgan's laws. This is the principle of the excluded third (or excluded middle), which asserts that, for every proposition p, either p or not p; and equivalently that, for every p, not not p implies p. This principle is basic to classical logic and had already been enunciated by Aristotle, though with some reservations, as he pointed out that the statement "there will be a sea battle tomorrow" is neither true nor false.

Brouwer did not claim that the principle of the excluded third always fails, only that it may fail in the presence of infinite sets. Of two natural numbers x and y one can always decide whether $x = y$ or $x \neq y$, but of two real numbers this may not be possible, as one might have to know an infinite number of digits of their decimal expansions. Similar objections apply to De Morgan's laws, a consequence of the principle of the excluded third. For a finite set A, if it has been shown that the assertion $\forall_{x \in A} \neg\varphi(x)$ leads to a contradiction, $\exists_{x \in A}\varphi(x)$ can be verified by looking at each element of A in turn; *i.e.*, the statement that no members of a given set have a certain property can be disproved by examining in turn each element of the set. For an infinite set A, there is no way in which such an inspection can be carried out.

Brouwer's philosophy of mathematics is called intuitionism. Although Brouwer himself felt that mathematics was language-independent, his disciple Arend Heyting (1898–1980) set up a formal language for first-order intuitionistic arithmetic. Some of Brouwer's later followers even studied intuitionistic type theory (see below), which differs from classical type theory only by the absence of a single axiom (double negation):

$$\forall_{x \in \Omega}(\neg\neg x \supset x),$$

where Ω is the type of truth-values.

While it cannot be said that many practicing mathematicians have followed Brouwer in rejecting this principle on philosophical grounds, it came as a great surprise to people working in category theory that certain important categories called topoi (singular: topos; see below) have associated with them a language that is intuitionistic in general. In consequence of this fact, a theorem about sets proved constructively was immediately seen to be valid not only for sets but also for sheaves, which, however, lie beyond the scope of this article.

The moderate form of intuitionism considered here embraces Kronecker's constructivism but not the more extreme position of finitism. According to this view, which goes back to Aristotle, infinite sets do not exist, except potentially. In fact, it is precisely in the presence of infinite sets that intuitionists drop the classical principle of the excluded third.

An even more extreme position, called ultrafinitism, maintains that even very large numbers do not exist, say numbers greater than $10^{(10^{10})}$. Of course, the vast majority of mathematicians reject this view by referring to $10^{(10^{10})} + 1$, but the true believers have subtle ways of getting around this objection, which, however, lie beyond the scope of this discussion.

Ultrafinitism

Other logics. While intuitionistic logic is obtained from classical logic by dropping the principle of the excluded third, other logics have also been proposed, though none has had a comparable impact on the foundations of mathematics. One may mention many-valued, or multivalued, logics, which admit a finite number of truth-values; fuzzy logic, with an imprecise membership relationship (though, paradoxically, a precise equality relation); and quantum logic, where conjunction may be only partially defined and implication may not be defined at all. Perhaps more important have been various so-called substructural logics in which the usual properties of the deduction symbol are weakened: relevance logic is studied by philosophers, linear logic by computer scientists, and a noncommutative version of the latter by linguists.

Formalism. Russell's discovery of a hidden contradiction in Frege's attempt to formalize set theory, with the help of his simple comprehension scheme, caused some mathematicians to wonder how one could make sure that no other contradictions existed. Hilbert's program, called formalism, was to concentrate on the formal language of mathematics and to study its syntax. In particular, the consistency of mathematics, which may be taken, for instance, to be the metamathematical assertion that the mathematical statement $0 = 1$ is not provable, ought to be a metatheorem—that is, provable within the syntax of mathematics. This formalization project made sense only if the syntax of mathematics was consistent, for otherwise every syntactical statement would be provable, including that which asserts the consistency of mathematics.

Unfortunately, a consequence of Gödel's incompleteness theorem (see below) is that the consistency of mathematics can be proved only in a language which is stronger than the language of mathematics itself. Yet, formalism is not dead—in fact, most pure mathematicians are tacit formalists—but the naive attempt to prove the consistency of mathematics in a weaker system had to be abandoned.

While no one, except an extremist intuitionist, will deny the importance of the language of mathematics, most mathematicians are also philosophical realists who believe that the words of this language denote entities in the real world. Following the Swiss mathematician Paul Bernays (1888–1977), this position is also called Platonism, since Plato believed that mathematical entities really exist.

Gödel. Implicit in Hilbert's program had been the hope that the syntactic notion of provability would capture the semantic notion of truth. Gödel came up with the surprising discovery that this was not the case for type theory and related languages adequate for arithmetic, as long as the following assumptions are insisted upon:

1. The set of theorems (provable statements) is effectively enumerable, by virtue of the notion of proof being decidable.
2. The set of true statements of mathematics is ω-complete in the following sense: given any formula $\varphi(x)$, containing a free variable x of type N, the universal statement $\forall_{x \in N}\varphi(x)$ will be true if $\varphi(n)$ is true for each numeral n—that is, for $n = 0$, $n = S0$, $n = SS0$, and so on.
3. The language is consistent.

Actually, Gödel also made a somewhat stronger assumption, which, as the American mathematician J. Barkley Rosser later showed, could be replaced by assuming consistency. Gödel's ingenious argument was based on the observation that syntactical statements about the language of mathematics can be translated into statements of arithmetic, hence into the language of mathematics. It was partly inspired by an argument that supposedly goes back to the ancient Greeks and which went something like this: Epimenides says that all Cretans are liars; Epimenides is a Cretan; hence Epimenides is a liar. Under the assumptions 1 and 2, Gödel constructed a mathematical statement g that is true but not provable. If it is assumed that all theorems are true, it follows that neither g nor $\neg g$ is a theorem.

The liar paradox

No mathematician doubts assumption 1; by looking at a purported proof of a theorem, suitably formalized, it is possible for a mathematician, or even a computer, to tell whether it is a proof. By listing all proofs in, say, alphabetic order, an effective enumeration of all theorems is obtained. Classical mathematicians also accept assumption 2 and therefore reluctantly agree with Gödel that, contrary to Hilbert's expectation, there are true mathematical statements which are not provable.

However, moderate intuitionists could draw a different conclusion, because they are not committed to assumption 2. To them, the truth of the universal statement $\forall_{x \in N}\varphi(x)$ can be known only if the truth of $\varphi(n)$ is known, for each natural number n, in a uniform way. This would not be the case, for example, if the proof of $\varphi(n)$ increases in difficulty, hence in length, with n. Moderate intuitionists might therefore identify truth with provability and not be bothered by the fact that neither g nor $\neg g$ is true, as they would not believe in the principle of the excluded third in the first place.

Intuitionists have always believed that, for a statement to be true, its truth must be knowable. Moreover, moderate intuitionists might concede to formalists that to say that a statement is known to be true is to say that it has been proved. Still, some intuitionists do not accept the above argument. Claiming that mathematics is language-independent, intuitionists would state that in Gödel's metamathematical proof of his incompleteness theorem, citing ω-completeness to establish the truth of a universal statement yields a uniform proof of the latter after all.

Absolute truth or truth within a model

Gödel considered himself to be a Platonist, inasmuch as he believed in a notion of absolute truth. He took it for granted, as do many mathematicians, that the set of true statements is ω-complete. Other logicians are more skeptical and want to replace the notion of truth by that of truth in a model. In fact, Gödel himself, in his completeness theorem, had shown that for a mathematical statement to be provable it is necessary and sufficient that it be true in every model. His incompleteness theorem now showed that truth in every ω-complete model is not sufficient for provability. This point will be returned to later, as the notion of model for type theory is most easily formulated with the help of category theory, although this is not the way Gödel himself proceeded. See below *Gödel and category theory*.

Recursive definitions. Peano had observed that addition of natural numbers can be defined recursively thus:

$$x + 0 = x,\ x + Sy = S(x + y).$$

Other numerical functions $\mathbf{N}^k \to \mathbf{N}$ that can be defined with the help of such a recursion scheme (and with the help of 0, S, and substitution) are called primitive recursive. Gödel used this concept to make precise what he meant by "effectively enumerable." A set of natural numbers is said to be recursively enumerable if it consists of all $f(n)$ with $n \in \mathbf{N}$, where $f: \mathbf{N} \to \mathbf{N}$ is a primitive recursive function.

Recursive enumerablity

This notion can easily be extended to subsets of $\mathbf{N}^k$ and, by a simple trick called arithmetization, to sets of strings of words in a language. Thus Gödel was able to assert that the set of theorems of mathematics is recursively enumerable, and, more recently, the American linguist Noam Chomsky (b. 1928) could say that the set of grammatical sentences of a natural language, such as English, is recursively enumerable.

It is not difficult to show that all primitive recursive functions can be calculated. For example, to calculate $x + y$ when $x = 3$ and $y = 2$, making use of Peano's recursive definition of $x + y$ and of the definitions $1 = S0$, $2 = S1$, and so on, one proceeds as follows:

$$\begin{aligned} 3 + 2 &= S2 + S1 = S(S2 + 1) = S(S2 + S0) \\ &= SS(S2 + 0) = SSS2 = SS3 = S4 = 5. \end{aligned}$$

But primitive recursive functions are not the only numerical functions that can be calculated. More general are the recursive functions, where $f: \mathbf{N} \to \mathbf{N}$ is said to be recursive if its graph is recursively enumerable—that is, if there exist primitive recursive functions $u,\ v: \mathbf{N} \to \mathbf{N}$ such that, for all natural numbers x and y, $y = f(x)$ if and only if, for some $z \in \mathbf{N}$, $x = u(z)$ and $y = v(z)$.

All recursive functions can be calculated with pencil and paper or, even more primitively, by moving pebbles (*calculi* in Latin) from one location to another, using some finite set of instructions, nowadays called a program. Conversely, only recursive functions can be so calculated, or computed by a theoretical machine introduced by the English mathematician Alan Turing (1912–54), or by a modern computer, for that matter. The Church-Turing thesis asserts that the informal notion of calculability is completely captured by the formal notion of recursive functions and hence, in theory, replicable by a machine.

The Church-Turing thesis

Gödel's incompleteness theorem had proved that any useful formal mathematical system will contain undecidable propositions—propositions which can be neither proved nor disproved. Church and Turing, while seeking an algorithmic (mechanical) test for deciding theoremhood and thus potentially deleting nontheorems, proved independently, in 1936, that such an algorithmic method was impossible for the first-order predicate logic (see LOGIC, THE HISTORY AND KINDS OF: *20th-century logic*). The Church-Turing theorem of undecidability, combined with the related result of the Polish-born American mathematician Alfred Tarski (1902–83) on undecidability of truth, eliminated the possibility of a purely mechanical device replacing mathematicians.

Computers and proof. While many mathematicians use computers only as word processors and for the purpose of communication, computer-assisted computations can be useful for discovering potential theorems. For example, the prime number theorem was first suggested as the result of extensive hand calculations on the prime numbers up to 3,000,000 by the Swiss mathematician Leonhard Euler (1707–83), a process that would have been greatly facili-

tated by the availability of a modern computer. Computers may also be helpful in completing proofs when there are a large number of cases to be considered. The renowned computer-aided proof of the four-colour mapping theorem by the American mathematicians Kenneth Appel (b. 1932) and Wolfgang Haken (b. 1928) even goes beyond this, as the computer helped to determine which cases were to be considered in the next step of the proof. Yet, in principle, computers cannot be asked to discover proofs, except in very restricted areas of mathematics—such as elementary Euclidean geometry—where the set of theorems happens to be recursive, as was proved by Tarski.

Four-colour mapping theorem

As the result of earlier investigations by Turing, Church, the American mathematician Haskell Brooks Curry (1900–82), and others, computer science has itself become a branch of mathematics. Thus, in theoretical computer science, the objects of study are not just theorems but also their proofs, as well as calculations, programs, and algorithms. Theoretical computer science turns out to have a close connection to category theory. Although this lies beyond the scope of this article, an indication will be given below.

CATEGORY THEORY

Abstraction in mathematics. One recent tendency in the development of mathematics has been the gradual process of abstraction. The Norwegian mathematician Niels Henrik Abel (1802–29) proved that equations of the fifth degree cannot, in general, be solved by radicals. The French mathematician Évariste Galois (1811–32), motivated in part by Abel's work, introduced certain groups of permutations to determine the necessary conditions for a polynomial equation to be solvable. These concrete groups soon gave rise to abstract groups, which were described axiomatically. Then it was realized that to study groups it was necessary to look at the relation between different groups—in particular, at the homomorphisms which map one group into another while preserving the group operations. Thus people began to study what is now called the concrete category of groups, whose objects are groups and whose arrows are homomorphisms. It did not take long for concrete categories to be replaced by abstract categories, again described axiomatically. (For an introduction, see ALGEBRA: *Groups.*)

Categories

The important notion of a category was introduced by Samuel Eilenberg and Saunders Mac Lane at the end of World War II. These modern categories must be distinguished from Aristotle's categories, which are better called types in the present context. A category has not only objects but also arrows (referred to also as morphisms, transformations, or mappings) between them. For a more general introduction to categories, see ALGEBRA: *Categories.*

Many categories have as objects sets endowed with some structure and arrows, which preserve this structure. Thus, there exist the categories of sets (with empty structure) and mappings, of groups and group-homomorphisms, of rings and ring-homomorphisms, of vector spaces and linear transformations, of topological spaces and continuous mappings, and so on. There even exists, at a still more abstract level, the category of (small) categories and functors, as the morphisms between categories are called, which preserve relationships among the objects and arrows.

Functors

Not all categories can be viewed in this concrete way. For example, the formulas of a deductive system may be seen as objects of a category whose arrows $f: A \to B$ are deductions of B from A. In fact, this point of view is important in theoretical computer science, where formulas are thought of as types and deductions as operations.

More formally, a category consists of (1) a collection of objects $A, B, C, \ldots$, (2) for each ordered pair of objects in the collection an associated collection of transformations including the identity $1_A: A \to A$, and (3) an associated law of composition for each ordered triple of objects in the category such that for $f: A \to B$ and $g: B \to C$ the composition gf (or $g \circ f$) is a transformation from A to C—*i.e.*, $gf: A \to C$. Additionally, the associative law and the identities are required to hold (where the compositions are defined)—*i.e.*, $h(gf) = (hg)f$ and $1_B f = f = f 1_A$.

In a sense, the objects of an abstract category have no windows, like the monads of Leibniz. To infer the interior of an object A one need only look at all the arrows from other objects to A. For example, in the category of sets, elements of a set A may be represented by arrows from a typical one-element set into A. Similarly, in the category of small categories, if **1** is the category with one object and no nonidentity arrows, the objects of a category **A** may be identified with the functors $\mathbf{1} \to \mathbf{A}$. Moreover, if **2** is the category with two objects and one nonidentity arrow, the arrows of **A** may be identified with the functors $\mathbf{2} \to \mathbf{A}$.

Isomorphic structures. An arrow $f: A \to B$ is called an isomorphism if there is an arrow $g: B \to A$ inverse to f—that is, such that $g \circ f = 1_A$ and $f \circ g = 1_B$. This is written $A \cong B$, and A and B are called isomorphic, meaning that they have essentially the same structure and that there is no need to distinguish between them. Inasmuch as mathematical entities are objects of categories, they are given only up to isomorphism. Their traditional set-theoretical constructions, aside from serving a useful purpose in showing consistency, are really irrelevant.

For example, in the usual construction of the ring of integers, an integer is defined as an equivalence class of pairs (m,n) of natural numbers, where (m,n) is equivalent to (m',n') if and only if $m + n' = m' + n$. The idea is that the equivalence class of (m,n) is to be viewed as $m - n$. What is important to a categorist, however, is that the ring **Z** of integers is an initial object in the category of rings and homomorphisms—that is, that for every ring **R** there is a unique homomorphism $\mathbf{Z} \to \mathbf{R}$. Seen in this way, **Z** is given only up to isomorphism. In the same spirit, it should be said not that **Z** is contained in the field **Q** of rational numbers but only that the homomorphism $\mathbf{Z} \to \mathbf{Q}$ is one-to-one. Likewise, it makes no sense to speak of the set-theoretical intersection of π and $\sqrt{-1}$, if both are expressed as sets of sets of sets (ad infinitum).

Adjoint functors

Of special interest in foundations and elsewhere are adjoint functors (F,G). These are pairs of functors between two categories $\mathcal{A}$ and $\mathcal{B}$, which go in opposite directions such that a one-to-one correspondence exists between the set of arrows $F(A) \to B$ in $\mathcal{B}$ and the set of arrows $A \to G(B)$ in $\mathcal{A}$—that is, such that the sets are isomorphic.

Topos theory. The original purpose of category theory had been to make precise certain technical notions of algebra and topology and to present crucial results of divergent mathematical fields in an elegant and uniform way, but it soon became clear that categories had an important role to play in the foundations of mathematics. This observation was largely the contribution of the American mathematician F.W. Lawvere (b. 1937), who elaborated on the seminal work of the German-born French mathematician Alexandre Grothendieck (b. 1928) in algebraic geometry. At one time he considered using the category of (small) categories (and functors) itself for the foundations of mathematics. Though he did not abandon this idea, later he proposed a generalization of the category of sets (and mappings) instead.

Among the properties of the category of sets, Lawvere singled out certain crucial ones, only two of which are mentioned here:

1. There is a one-to-one correspondence between subsets B of A and their characteristic functions $\chi: A \to \{true, false\}$, where, for each element a of A, $\chi(a) = true$ if and only if a is in B.
2. Given an element a of A and a function $h: A \to A$, there is a unique function $f: \mathbf{N} \to A$ such that $f(n) = h^n(a)$.

Suitably axiomatized, a category with these properties is called an (elementary) topos. However, in general, the two-element set $\{true, false\}$ must be replaced by an object Ω with more than two truth-values, though a distinguished arrow into Ω is still labeled as *true*.

Intuitionistic type theories. Topoi are closely related to intuitionistic type theories. Such a theory is equipped with certain types, terms, and theorems.

Among the types there should be a type Ω for truth-values, a type N for natural numbers, and, for each type A, a type $\mathcal{P}(A)$ for all sets of entities of type A.

Among the terms there should be in particular:

1. The formulas $a = a'$ and $a \in \alpha$ of type Ω, if a and a' are of type A and α is of type $\mathcal{P}(A)$
2. The numerals 0 and Sn of type N, if the numeral n is of type N
3. The comprehension term $\{x \in A | \varphi(x)\}$ of type $\mathcal{P}(A)$, if $\varphi(x)$ is a formula of type Ω containing a free variable x of type A

The set of theorems should contain certain obvious axioms and be closed under certain obvious rules of inference, neither of which will be spelled out here.

At this point the reader may wonder what happened to the usual logical symbols. These can all be defined—for example, universal quantification

$$\forall_{x \in A}\varphi(x) \quad \text{as} \quad \{x \in A | \varphi(x)\} = \{x \in A | x = x\}$$

and disjunction

$$p \vee q \quad \text{as} \quad \forall_{t \in \Omega}((p \supset t) \supset ((q \supset t) \supset t)).$$

For a formal definition of implication see LOGIC, THE HISTORY AND KINDS OF: *Logic systems: Formal logic.*

Pure intuitionistic type theory

In general, the set of theorems will not be recursively enumerable. However, this will be the case for pure intuitionistic type theory $\mathcal{L}_0$, in which types, terms, and theorems are all defined inductively. In $\mathcal{L}_0$ there are no types, terms, or theorems other than those that follow from the definition of type theory. $\mathcal{L}_0$ is adequate for the constructive part of the usual elementary mathematics—arithmetic and analysis—but not for metamathematics, if this is to include a proof of Gödel's completeness theorem, and not for category theory, if this is to include the Yoneda embedding of a small category into a set-valued functor category.

Internal language. It turns out that each topos $\mathcal{T}$ has an internal language $L(\mathcal{T})$, an intuitionistic type theory whose types are objects and whose terms are arrows of $\mathcal{T}$. Conversely, every type theory $\mathcal{L}$ generates a topos $T(\mathcal{L})$, by the device of turning (equivalence classes of) terms into objects, which may be thought of as denoting sets.

Nominalists may be pleased to note that every topos $\mathcal{T}$ is equivalent (in the sense of category theory) to the topos generated by a language—namely, the internal language of $\mathcal{T}$. On the other hand, Platonists may observe that every type theory $\mathcal{L}$ has a conservative extension to the internal language of a topos—namely, the topos generated by $\mathcal{L}$, assuming that this topos exists in the real (ideal) world. Here, the phrase "conservative extension" means that $\mathcal{L}$ can be extended to $LT(\mathcal{L})$ without creating new theorems. The types of $LT(\mathcal{L})$ are names of sets in $\mathcal{L}$ and the terms of $LT(\mathcal{L})$ may be identified with names of sets in $\mathcal{L}$ for which it can be proved that they have exactly one element. This last observation provides a categorical version of Russell's theory of descriptions: if one can prove the unique existence of an x of type A in $\mathcal{L}$ such that $\varphi(x)$, then this unique x has a name in $LT(\mathcal{L})$.

The interpretation of a type theory $\mathcal{L}$ in a topos $\mathcal{T}$ means an arrow $\mathcal{L} \to L(\mathcal{T})$ in the category of type theories or, equivalently, an arrow $T(\mathcal{L}) \to \mathcal{T}$ in the category of topoi. Indeed, T and L constitute a pair of adjoint functors.

Gödel and category theory. It is now possible to reexamine Gödel's theorems from a categorical point of view. In a sense, every interpretation of $\mathcal{L}$ in a topos $\mathcal{T}$ may be considered as a model of $\mathcal{L}$, but this notion of model is too general, for example, when compared with the models of classical type theories studied by Henkin. Therefore, it is preferable to restrict $\mathcal{T}$ to being a special kind of topos called local. Given an arrow p into Ω in $\mathcal{T}$, then, p is *true* in $\mathcal{T}$ if p coincides with the arrow *true* in $\mathcal{T}$, or, equivalently, if p is a theorem in the internal language of $\mathcal{T}$. $\mathcal{T}$ is called a local topos provided that (1) $0 = 1$ is not true in $\mathcal{T}$, (2) $p \vee q$ is true in $\mathcal{T}$ only if p is true in $\mathcal{T}$ or q is true in $\mathcal{T}$, and (3) $\exists_{x \in A}\varphi(x)$ is true in $\mathcal{T}$ only if $\varphi(a)$ is true in $\mathcal{T}$ for some arrow $a : 1 \to A$ in $\mathcal{T}$. Here the statement $0 = 1$ in provision 1 can be replaced by any other contradiction—*e.g.*, by $\forall_{t \in \Omega}t$, which says that every proposition is true.

Gödel's completeness theorems

A model of $\mathcal{L}$ is an interpretation of $\mathcal{L}$ in a local topos $\mathcal{T}$. Gödel's completeness theorem, generalized to intuitionistic type theory, may now be stated as follows: A closed formula of $\mathcal{L}$ is a theorem if and only if it is true in every model of $\mathcal{L}$.

Gödel's incompleteness theorem, generalized likewise, says that, in the usual language of arithmetic, it is not enough to look only at ω-complete models: Assuming that $\mathcal{L}$ is consistent and that the theorems of $\mathcal{L}$ are recursively enumerable, with the help of a decidable notion of proof, there is a closed formula g in $\mathcal{L}$, which is true in every ω-complete model, yet g is not a theorem in $\mathcal{L}$.

The search for a distinguished model. A Platonist might still ask whether, among all the models of the language of mathematics, there is a distinguished model, which may be considered to be the world of mathematics. Take as the language $\mathcal{L}_0$ pure intuitionistic type theory (see above). It turns out, somewhat surprisingly, that the topos generated by $\mathcal{L}_0$ is a local topos; hence, the unique interpretation of $\mathcal{L}_0$ in the topos generated by it may serve as a distinguished model.

This so-called free topos has been constructed linguistically to satisfy any formalist, but it should also satisfy a moderate Platonist, one who is willing to abandon the principle of the excluded third, inasmuch as the free topos is the initial object in the category of all topoi. Hence, the free topos may be viewed, in the words of Leibniz, as the best of all possible worlds. More modestly speaking, the free topos is to an arbitrary topos like the ring of integers is to an arbitrary ring.

The language $\mathcal{L}_0$ should also satisfy any constructivist: if an existential statement $\exists_{x \in A}\varphi(x)$ can be proved in $\mathcal{L}_0$, then $\varphi(a)$ can be proved for some term a of type A; moreover, if $p \vee q$ can be proved, then either p can be proved or q can be proved.

The above argument would seem to make a strong case for the acceptance of pure intuitionistic type theory as the language of elementary mathematics—that is, of arithmetic and analysis—and hence for the acceptance of the free topos as the world of mathematics. Nonetheless, most practicing mathematicians prefer to stick to classical mathematics. In fact, classical arguments seem to be necessary for metamathematics—for example, in the usual proof of Gödel's completeness theorem—even for intuitionistic type theory.

In this connection, one celebrated consequence of Gödel's incompleteness theorem may be recalled, to wit: the consistency of $\mathcal{L}$ cannot be proved (via arithmetization) within $\mathcal{L}$. This is not to say that it cannot be proved in a stronger metalanguage. Indeed, to exhibit a single model of $\mathcal{L}$ would constitute such a proof.

It is more difficult to make a case for the classical world of mathematics, although this is what most mathematicians believe in. This ought to be a distinguished model of pure classical type theory $\mathcal{L}_1$. Unfortunately, Gödel's argument shows that the interpretation of $\mathcal{L}_1$ in the topos generated by it is not a model in this sense.

Boolean local topoi. A topos is said to be Boolean if its internal language is classical. It is named after the English mathematician George Boole (1815–64), who was the first to give an algebraic presentation of the classical calculus of propositions. A Boolean topos is local under the following circumstances. The disjunction property (2) holds in a Boolean topos if and only if, for every closed formula p, either p is true or $\neg p$ is true. Moreover, with the help of De Morgan's laws, the existence property (3) may then be rephrased thus: if $\varphi(a)$ is true for all closed terms a of type A, then $\forall_{x \in A}\varphi(x)$ is true. As it turns out, a Boolean local topos may be described more simply, without referring to the internal language, as a topos with the following property: if $f, g : A \to B$ are arrows such that $fa = ga$ for all $a : 1 \to A$, then $f = g$. (Here 1 is the so-called terminal object, with the property that, for each object C, there is a unique arrow $C \to 1$.) For the Boolean topos to be ω-complete requires furthermore that all numerals—that is, closed terms of type N in its internal language—be standard—that is, have the form 0, $S0$, $SS0$, and so on.

Of course, Gödel's completeness theorem shows that there are plenty of Boolean local topoi to model pure classical type theory in, but the usual proof of their existence requires nonconstructive arguments. It would be interesting to exhibit at least one such model constructively.

As a first step toward constructing a distinguished ω-complete Boolean model of $\mathcal{L}_1$ one might wish to de-

fine the notion of truth in $\mathcal{L}_1$, as induced by this model. Tarski had shown how truth can be defined for classical first-order arithmetic, a language that admits, aside from formulas, only terms of type N. Tarski achieved this essentially by incorporating ω-completeness into the definition of truth. It is not obvious whether his method can be extended to classical higher-order arithmetic—that is, to classical type theory. In fact, Tarski himself showed that the notion of truth is not definable (in a technical sense) in such a system. If his notion of definability corresponds to what is here meant by constructibility, then it is possible to conclude that, indeed, no Boolean model can be constructed.

The von Neumann universe

One may be tempted to consider as a candidate for the distinguished Boolean local topos the so-called von Neumann universe. This is defined as the union of a class of sets containing the empty set (the initial object in the category of sets) and closed under the power-set operation and under transfinite unions—thus, as a subcategory of the category of sets. But what is the category of sets if not the distinguished Boolean local topos being sought?

A better candidate may be Gödel's constructible universe, whose original purpose was to serve as a model of Zermelo-Fraenkel set theory in which the continuum hypothesis holds. It is formed like the von Neumann universe, except that the notion of subset, implicit in the power-set operation, is replaced by that of definable subset. Is it possible that this universe can be constructed syntactically, like the free topos, without reference to any previously given category of sets, or by a universal property?

Substitutional interpretation

In the internal language of a Boolean local topos, the logical connectives and quantifiers have their natural meanings. In particular, quantifiers admit a substitutional interpretation, a desirable property that has been discussed by philosophers (among them, Russell and the American logician Saul Kripke [b. 1941])—to wit: if an existential statement is true, then it can be witnessed by a term of appropriate type in the language; and a universal statement is true if it is witnessed by all terms of the appropriate type.

Note that, in the internal language of the free topos, and therefore in pure intuitionistic type theory, the substitutional interpretation is valid for existential quantifiers, by virtue of the free topos being local, but that it fails for universal quantifiers, in view of the absence of ω-completeness and the fact that in the free topos all numerals are standard. For a Boolean local topos, ω-completeness will also ensure that all numerals are standard, so that numerals mean exactly what they are intended to mean.

One distinguished model or many models. Some mathematicians do not believe that a distinguished world of mathematics should be sought at all, but rather that the multiplicity of such worlds should be looked at simultaneously. A major result in algebraic geometry, due to Alexandre Grothendieck, was the observation that every commutative ring may be viewed as a continuously variable local ring, as Lawvere would put it. In the same spirit, an amplified version of Gödel's completeness theorem would say that every topos may be viewed as a continuously variable local topos, provided sufficiently many variables (Henkin constants) are adjoined to its internal language. Put in more technical language, this makes the possible worlds of mathematics stalks of a sheaf. However, the question still remains as to where this sheaf lives if not in a distinguished world of mathematics or—perhaps better to say—metamathematics.

These observations suggest that the foundations of mathematics have not achieved a definitive shape but are still evolving; they form the subject of a lively debate among a small group of interested mathematicians, logicians, and philosophers.

BIBLIOGRAPHY. W.S. ANGLIN and J. LAMBEK, *The Heritage of Thales* (1995), a textbook aimed primarily at undergraduate mathematics students, deals with the history, philosophy, and foundations of mathematics and includes an elementary introduction to category theory. Collections of important readings and original articles include PAUL BENACERRAF and HILARY PUTNAM (eds.), *Philosophy of Mathematics: Selected Readings*, 2nd ed. (1983), treating the foundations of mathematics, the existence of mathematical objects, the notion of mathematical truth, and the concept of set; JAAKO HINTIKKA (ed.), *The Philosophy of Mathematics* (1969), which includes articles by Henkin on completeness, by Feferman on predicativity, by Robinson on the calculus, and by Tarski on elementary geometry; and JEAN VAN HEIJENOORT (compiler), *From Frege to Gödel: A Source Book in Mathematical Logic, 1879–1931* (1967, reissued 1977). BERTRAND RUSSELL, *A History of Western Philosophy and Its Connection with Political and Social Circumstances from the Earliest Times to the Present Day*, 2nd ed. (1961, reprinted 1991), an extremely readable work, portrays the relevant views of the pre-Socratics, Plato, Aristotle, Leibniz, and Kant. MARIO BUNGE, *Treatise on Basic Philosophy*, vol. 7, *Epistemology & Methodology III: Philosophy of Science and Technology*, part 1, *Formal and Physical Sciences* (1985), contains a discussion by a philosopher of the different philosophical schools in the foundations of mathematics. WILLIAM KNEALE and MARTHA KNEALE, *The Development of Logic* (1962, reprinted 1984), offers a thorough scholarly account of the growth of logic from ancient times to the contributions by Frege, Russell, Brouwer, Hilbert, and Gödel. SAUNDERS MAC LANE, *Mathematics, Form and Function* (1986), records the author's personal views on the form and function of mathematics as a background to the philosophy of mathematics, touching on many branches of mathematics. MICHAEL HALLETT, *Cantorian Set Theory and Limitation of Size* (1984), provides a scholarly account of Cantor's set theory and its further development by Fraenkel, Zermelo, and von Neumann. WILLIAM S. HATCHER, *Foundations of Mathematics* (1968), surveys different systems, including those of Frege, of Russell, of von Neumann, Bernays, and Gödel, and of Quine as well as Lawvere's category of categories. Y.I. MANIN (IU.I. MANIN), *A Course in Mathematical Logic*, trans. from Russian (1977), is addressed to mathematicians at a sophisticated level and presents the most significant discoveries up to 1977 concerning the continuum hypothesis, the nonexistence of algorithmic solutions, and other topics. GEORGE S. BOOLOS and RICHARD C. JEFFREY, *Computability and Logic*, 3rd ed. (1989), for graduate and advanced undergraduate philosophy or mathematics students, deals with computability, Gödel's theorems, and the definability of truth, among other topics. J. LAMBEK and P.J. SCOTT, *Introduction to Higher Order Categorical Logic* (1986), is an advanced textbook addressed to graduate students in mathematics and computer science in which the relationship between topoi and type theories is explored in detail and some of the metatheorems cited in this article are proved. The History of Mathematics

The following article is an account of how important parts of mathematics have developed historically. As a consequence of the exponential growth of science most of this mathematics has developed since the 15th century AD, and it is a historical fact that from the 15th century to the late 20th century new developments in mathematics have been largely concentrated in Europe and North America. For these reasons the bulk of this article is devoted to European developments since 1500.

This does not mean, however, that developments elsewhere have been unimportant. Indeed, to understand the history of mathematics in Europe it is necessary to know its history at least in Mesopotamia and Egypt, in ancient Greece, and in Islāmic civilization from the 9th to the 15th centuries. The way in which these civilizations influenced one another, and the important direct contributions Greece and Islām made to later developments, are discussed in the first parts of this article.

India's contributions to the development of contemporary mathematics were made through the considerable influence of Indian achievements on Islāmic mathematics during its formative years. In order to provide a portrait of the mathematical achievements of one major Asian civilization, the article contains an overview of some of the principal periods and achievements of mathematics in China.

It is important to be aware of the character of the sources for the study of the history of mathematics. The history of Mesopotamian and Egyptian mathematics is based on the many extant original documents written by scribes. Although in the case of Egypt these documents are few, they are all of a type and leave little doubt that Egyptian mathematics was, on the whole, elementary and profoundly practical in its orientation. For Mesopotamian mathematics, on the other hand, there are a large number of clay tablets, which reveal mathematical achievements of a much higher order than those of the Egyptians. The tablets indicate that the Mesopotamians had a great deal of remarkable mathematical knowledge, although they offer no evidence that this knowledge was organized into a deductive system. Future research may reveal more about the early development of mathematics in Mesopotamia or about its influence on Greek mathematics, but it seems likely that this picture of Mesopotamian mathematics will stand.

From the period before Alexander the Great no Greek mathematical documents have been preserved except for fragmentary paraphrases, and even for the subsequent period it is well to remember that the oldest copies of Euclid's *Elements* are in Byzantine manuscripts dating from the 10th century AD. This stands in complete contrast to the situation described above for Egyptian and Babylonian documents. Although in general outline the present account of Greek mathematics is secure, in such important matters as the origin of the axiomatic method, the pre-Euclidean theory of ratios, and the discovery of the conic sections, historians have given competing accounts based on fragmentary texts, quotations of early writings culled from nonmathematical sources, and a considerable amount of conjecture.

Many important treatises from the early period of Islāmic mathematics have not survived or have survived only in Latin translations, so that there are still many unanswered questions about the relationship between early Islāmic mathematics and the mathematics of Greece and India. In addition, the amount of surviving material from later centuries is so large in comparison with that which has been studied that it is not yet possible to offer any sure judgment of what medieval Islāmic mathematics did not contain, and this means that it is not yet possible to evaluate with any assurance what was original in European mathematics from the 11th to the 15th century.

In modern times the invention of printing has largely solved the problem of obtaining secure texts and has allowed historians of mathematics to concentrate their editorial efforts on the correspondence or the unpublished works of mathematicians. However, the exponential growth of mathematics means that, for the period from the 19th century on, historians are able to treat only the major figures in any detail. In addition there is, as the period gets nearer the present, the problem of perspective. Mathematics, like any other human activity, has its fashions, and the nearer one is to a given period, the more likely these fashions are to look like the wave of the future. For this reason, the present article makes no attempt to assess the most recent developments in the subject.

The article is divided into the following sections:

Mathematics in ancient Mesopotamia

Until the 1920s it was commonly supposed that mathematics had its birth among the ancient Greeks. What was known of earlier traditions, such as the Egyptian as represented by the Rhind Papyrus (itself edited for the first time only in 1877), offered at best a meagre precedent. This impression gave way to a very different view as Orientalists succeeded in deciphering and interpreting the technical materials from ancient Mesopotamia.

Owing to the durability of the Mesopotamian scribes' clay tablets, the surviving evidence of this culture is substantial. Existing specimens of mathematics represent all the major eras—the Sumerian kingdoms of the 3rd millennium BC, the Akkadian and Babylonian regimes (2nd millennium), and the empires of the Assyrians (early 1st millennium), Persians (6th through 4th centuries BC), and Greeks (3rd century BC to 1st century AD). The level of competence was already high as early as the Old Babylonian dynasty, the time of the lawgiver king Hammurabi (*c.* 18th century BC), but after that there were few notable advances. The application of mathematics to astronomy, however, flourished during the Persian and Seleucid (Greek) periods.

The numeral system and arithmetic operations. Unlike the Egyptians, the mathematicians of the Old Babylonian period went far beyond the immediate challenges of their official accounting duties; for example, they introduced a versatile numeral system, which, like the modern system, exploited the notion of place value, and they developed computational methods that took advantage of this means of expressing numbers; they solved linear and quadratic problems by methods much like those now used in school algebra; their success with the study of what are now called Pythagorean number triples was a remarkable feat in number theory. The scribes who made such discoveries must have believed mathematics to be worthy of study in its own right, not just as a practical tool.

The older Sumerian system of numerals followed an additive decimal (base-10) principle similar to that of the Egyptians. But the Old Babylonian system converted this into a place-value system with the base of 60 (sexagesimal). The reasons for the choice of 60 are obscure, but one good mathematical reason might have been the existence of so many divisors (2, 3, 4, and 5, and some multiples) of the base, which would have greatly facilitated the operation of division. For numbers from 1 to 59, the symbols 𒁹 for 1 and 𒌋 for 10 were combined in the simple additive manner (*e.g.*, 𒌋𒌋𒌋𒁹𒁹 represented 32). But, to express larger values, the Babylonians applied the concept of place value: for example, 60 was written as 𒁹, 70 as 𒁹𒌋, 80 as 𒁹𒌋𒌋, and so on. In fact, 𒁹 could represent any power of 60. The context determined which power was intended. The Babylonians appear to have developed a placeholder symbol that functioned as a zero by the 3rd century BC, but its precise meaning and use is still uncertain. Furthermore, they had no mark to separate numbers into integral and fractional parts (as with the modern decimal point). Thus, the three-place numeral 3 7 30 could represent $3\frac{1}{8}$ (*i.e.*, $3 + 7/60 + 30/60^2$), $187\frac{1}{2}$ (*i.e.*, $3 \times 60 + 7 + 30/60$), 11,250 (*i.e.*, $3 \times 60^2 + 7 \times 60 + 30$), or a multiple of these numbers by any power of 60.

The four arithmetic operations were performed in the same way as in the modern decimal system, except that carrying occurred whenever a sum reached 60 rather than 10. Multiplication was facilitated by means of tables; one typical tablet lists the multiples of a number by 1, 2, 3, . . . , 19, 20, 30, 40, and 50. To multiply two numbers several places long, the scribe first broke the problem down into several multiplications, each by a one-place number, and then looked up the value of each product in the appropriate tables. He found the answer to the problem by adding up these intermediate results. These tables also assisted in division, for the values that head them were all reciprocals of regular numbers. Multiplication

Regular numbers are those whose prime factors divide the base; the reciprocals of such numbers thus have only a finite number of places (by contrast, the reciprocals of nonregular numbers produce an infinitely repeating numeral). In base 10, for example, only numbers with factors of 2 and 5 (*e.g.*, 8 or 50) are regular, and the reciprocals ($\frac{1}{8} = 0.125$, $\frac{1}{50} = 0.02$) have finite expressions; but the reciprocals of other numbers (such as 3 and 7) repeat infinitely ($0.\overline{3}$ and $0.\overline{142857}$, respectively, where the bar indicates the digits that continually repeat). In base 60, only numbers with factors of 2, 3, and 5 are regular; for example, 6 and 54 are regular, so that their reciprocals (10 and 1 6 40) are finite. The entries in the multiplication table for 1 6 40 are thus simultaneously multiples of its reciprocal $\frac{1}{54}$. To divide a number by any regular number, then, one can consult the table of multiples for its reciprocal.

An interesting tablet in the collection of Yale University (see Figure 1) shows a square with its diagonals; on one side is written "30," under one diagonal "42 25 35," and right along the same diagonal "1 24 51 10" (*i.e.*, $1 + 24/60 + 51/60^2 + 10/60^3$). This third number is the correct value of $\sqrt{2}$ to four sexagesimal places (equivalent in the decimal system to 1.414213 . . . , which is too low by only 1 in the seventh place), while the second number is the product of the third number and the first and so gives the length of the diagonal when the side is 30. The scribe thus appears to have known an equivalent of the familiar long method of finding square roots. An additional element of sophistication is that, by choosing 30 (that is, $\frac{1}{2}$) for the side, the scribe obtained as the diagonal the reciprocal of

Yale Babylonian Collection

Figure 1: Babylonian mathematical tablet.

the value of $\sqrt{2}$ (since $\sqrt{2}/2 = 1/\sqrt{2}$), a result useful for purposes of division.

Geometric and algebraic problems. In a Babylonian tablet now in Berlin, the diagonal of a rectangle of sides 40 and 10 is solved as $40 + 10^2/(2 \times 40)$. Here, a very effective approximating rule is being used (that the square root of the sum of $a^2 + b^2$ can be estimated as $a + b^2/2a$), the same rule found frequently in later Greek geometric writings. Both these examples for roots illustrate the Babylonians' arithmetic approach in geometry. They also show that the Babylonians were aware of the relation between the hypotenuse and the two legs of a right triangle (now commonly known as the Pythagorean theorem) more than a thousand years before the Greeks used it.

A type of problem that occurs frequently in the Babylonian tablets seeks the base and height of a rectangle, where their product and sum have specified values. From the given information the scribe worked out the difference, since $(b-h)^2 = (b+h)^2 - 4bh$. In the same way, if the product and difference were given, the sum could be found.

Quadratic problems

And, once both the sum and difference were known, each side could be determined, for $2b = (b+h) + (b-h)$ and $2h = (b+h) - (b-h)$. This procedure is equivalent to a solution of the general quadratic in one unknown. In some places, however, the Babylonian scribes solved quadratic problems in terms of a single unknown, just as would now be done by means of the quadratic formula.

Although these Babylonian quadratic procedures have often been described as the earliest appearance of algebra, there are important distinctions. The scribes lacked an algebraic symbolism; although they must certainly have understood that their solution procedures were general, they always presented them in terms of particular cases, rather than as the working through of general formulas and identities. They thus lacked the means for presenting general derivations and proofs of their solution procedures. Their use of sequential procedures rather than formulas, however, is less likely to detract from an evaluation of their effort now that algorithmic methods much like theirs have become commonplace through the development of computers.

As mentioned above, the Babylonian scribes knew that the base (b), height (h), and diagonal (d) of a rectangle satisfy the relation $b^2 + h^2 = d^2$. If one selects values at random for two of the terms, the third will usually be irrational, but it is possible to find cases in which all three terms are integers: for example, 3, 4, 5 and 5, 12, 13. (Such solutions are sometimes called Pythagorean triples.) A tablet in the Columbia University Collection presents a list of 15 such triples (decimal equivalents are shown in parentheses at the right; the gaps in the expressions for h, b, and d separate the place values in the sexagesimal numerals):

h	b	d			
2	1 59	2 49	(120	119	169)
57 36	56 7	1 20 45	(3,456	3,367	4,825)
1 20	1 16 41	1 50 49	(4,800	4,601	6,649)
3 45	3 31 49	5 9 1	(13,500	12,709	18,541)
1 12	1 5	1 37	(72	65	97)
...	...	...	...	...	...
1 30	56	1 46	(90	56	106)

(The entries in the column for h have to be computed from the values for b and d, for they do not appear on the tablet; but they must once have existed on a portion now missing.) The ordering of the lines becomes clear from another column, listing the values of d^2/h^2 (brackets indicate figures that are lost or illegible), which form a continually decreasing sequence: [1 59 0] 15, [1 56 56] 58 14 50 6 15, . . . , [1] 23 13 46 40. Accordingly, the angle formed between the diagonal and the base in this sequence increases continually from just over 45° to just under 60°. Other properties of the sequence suggest that the scribe knew the general procedure for finding all such number triples—that for any integers p and q, $2d/h = p/q + q/p$ and $2b/h = p/q - q/p$. (In the table, the implied values p and q turn out to be regular numbers falling in the standard set of reciprocals, as mentioned above in connection with the multiplication tables.) Scholars are still debating nuances of the construction and the intended use of this table, but no one questions the high level of expertise implied by it.

Mathematical astronomy. The sexagesimal method developed by the Babylonians has a far greater computational potential than what was actually needed for the older problem texts. With the development of mathematical astronomy in the Seleucid period, however, it became indispensable. The astronomers sought to predict future occurrences of important phenomena, such as lunar eclipses and critical points in planetary cycles (conjunctions, oppositions, stationary points, and first and last visibility). They devised a technique for computing these positions (expressed in terms of degrees of latitude and longitude, measured relative to the path of the Sun's apparent annual motion) by successively adding appropriate terms in arithmetic progression. The results were then organized into a table listing positions as far ahead as the scribe chose. (Although the method is purely arithmetic, one can interpret it graphically: the tabulated values form a linear "zigzag" approximation to what is actually a sinusoidal variation.) While observations extending over centuries are required for finding the necessary parameters (*e.g.*, periods, angular range between maximum and minimum values, and the like), only the computational apparatus at their disposal made the astronomers' forecasting effort possible.

Calculation of planetary positions

Within a relatively short time (perhaps only a century or less), the elements of this system came into the hands of the Greeks. Although Hipparchus (2nd century BC) favoured the geometric approach of his Greek predecessors, he took over parameters from the Mesopotamians and adopted their sexagesimal style of computation. Through the Greeks it passed to Arabic scientists in the Middle Ages and thence to Europe, where it remained prominent in mathematical astronomy during the Renaissance and the early modern period. To this day it persists in the use of minutes and seconds to measure time and angles.

Aspects of the Old Babylonian mathematics may have come to the Greeks before this, early in the 5th century BC, the formative period of Greek geometry. There are a number of parallels that scholars have noted: for example, the Greek technique of "application of area" (see below) corresponded to the Babylonian quadratic methods (although in a geometric, not arithmetic, form). Further, the Babylonian rule for estimating square roots was widely used in Greek geometric computations, and there may also have been some shared nuances of technical terminology. Although details of the timing and manner of such a transmission are obscure because of the absence of explicit documentation, it seems that Western mathematics, while stemming largely from the Greeks, is considerably indebted to the older Mesopotamians.

Mathematics in ancient Egypt

The introduction of writing in Egypt in the predynastic period (*c.* 3000 BC) brought with it the formation of a special class of literate professionals, the scribes. By virtue of their writing skills, the scribes took on all the duties of a civil service: record keeping, tax accounting, the management of public works (building projects and the like), even the prosecution of war through overseeing military supplies and payrolls. Young men enrolled in scribal schools to learn the essentials of the trade, which included not only reading and writing but also the basics of mathematics.

One of the texts popular as a copy exercise in the schools of the New Kingdom (13th century BC) was a satirical letter in which one scribe, Hori, taunts his rival, Amenem-opet, for his incompetence as an adviser and manager. "You are the clever scribe at the head of the troops," Hori chides at one point; "a ramp is to be built, 730 cubits long, 55 cubits wide, with 120 compartments—it is 60 cubits high, 30 cubits in the middle . . . and the generals and the scribes turn to you and say, 'You are a clever scribe, your name is famous. Is there anything you don't know? Answer us, how many bricks are needed?' Let each compartment be 30 cubits by 7 cubits."

This problem, and three others like it in the same letter, cannot be solved without further data. But the point of

the humour is clear, as Hori challenges his rival with these hard, but typical, tasks.

Mathematical texts

What is known of Egyptian mathematics tallies well with the tests posed by the scribe Hori. The information comes primarily from two long papyrus documents that once served as textbooks within scribal schools. The Rhind Papyrus (in the British Museum) is a copy made in the 17th century BC of a text two centuries older still. In it is found a long table of fractional parts to help with division, followed by the solutions of 84 specific problems in arithmetic and geometry. The Golenishchev Papyrus (in the Moscow Museum of Fine Arts), dating from the 19th century BC, presents 25 problems of a similar type. These problems reflect well the functions the scribes would perform, for they deal with how to distribute beer and bread as wages, for example, or how to measure the areas of fields or the volumes of pyramids and other solids.

The numeral system and arithmetic operations. The Egyptians, like the Romans after them, expressed numbers according to a decimal scheme, using separate symbols for 1, 10, 100, 1,000, and so on; each symbol appeared in the expression for a number as many times as the value it represented occurred in the number itself. For example,  stood for 24. This rather cumbersome notation was used within the hieroglyphic writing found in stone inscriptions and other formal texts, but in the papyrus documents the scribes employed a more convenient abbreviated script, called hieratic writing, where, for example, 24 was written  .

In such a system, addition and subtraction amount to counting how many symbols of each kind there are in the numerical expressions and then rewriting with the resulting number of symbols. The texts that survive do not reveal what, if any, special procedures the scribes used to assist in this. But for multiplication they introduced a method of successive doubling. For example, to multiply 28 by 11, one constructs a table of multiples of 28 like the following:

1	28
2	56
4	112
8	224
16	448
...	...

The several entries in the first column that together sum to 11 (*i.e.*, 8, 2, and 1) are checked off. The product is then found by adding up the multiples corresponding to these entries; thus, $224 + 56 + 28 = 308$, the desired product.

To divide 308 by 28, the Egyptians applied the same procedure in reverse. Using the same table as in the multiplication problem, one can see that 8 produces the largest multiple of 28 that is less then 308 (for the entry at 16 is already 448), and 8 is checked off. The process is then repeated, this time for the remainder (84) obtained by subtracting the entry at 8 (224) from the original number (308). This, however, is already smaller than the entry at 4, which consequently is ignored, but it is greater than the entry at 2 (56), which is then checked off. The process is repeated again for the remainder obtained by subtracting 56 from the previous remainder of 84, or 28, which also happens to exactly equal the entry at 1 and which is then checked off. The entries that have been checked off are added up, yielding the quotient: $8 + 2 + 1 = 11$. (In most cases, of course, there is a remainder that is less than the divisor.)

For larger numbers, this procedure can be improved by considering multiples of one of the factors by 10, 20, . . . or even by higher orders of magnitude (100, 1,000, . . .), as necessary (in the Egyptian decimal notation, these multiples are easy to work out). Thus, one can find the product of 28 by 27 by setting out the multiples of 28 by 1, 2, 4, 8, 10, and 20. Since the entries 1, 2, 4, and 20 add up to 27, one has only to add up the corresponding multiples to find the answer.

Computations involving fractions

Computations involving fractions are carried out under the restriction to unit parts (that is, fractions that in modern notation are written with 1 as the numerator). To express the result of dividing 4 by 7, for instance, which in modern notation is simply $4/7$, the scribe wrote $1/2 + 1/14$. The procedure for finding quotients in this form merely extends the usual method for the division of integers, where one now inspects the entries for $2/3$, $1/3$, $1/6$, etc., and $1/2$, $1/4$, $1/8$, etc., until the corresponding multiples of the divisor sum to the dividend. (The scribes included $2/3$, one may observe, even though it is not a unit fraction.) In practice, the procedure can sometimes become quite complicated (for example, the value for $2/29$ is given in the Rhind Papyrus as $1/24 + 1/58 + 1/174 + 1/232$) and can be worked out in different ways (for example, the same $2/29$ might be found as $1/15 + 1/435$ or as $1/16 + 1/232 + 1/464$, etc.). A considerable portion of the papyrus texts is devoted to tables to facilitate the finding of such unit-fraction values.

These elementary operations are all that one needs for solving the arithmetic problems in the papyri. For example, "to divide 6 loaves among 10 men" (Rhind Papyrus, problem 3), one merely divides to get the answer $1/2 + 1/10$. In one group of problems an interesting trick is used: "A quantity (*aha*) and its 7th together make 19—what is it?" (Rhind Papyrus, problem 24). Here one first supposes the quantity to be 7: since $1\,1/7$ of it becomes 8, not 19, one takes $19/8$ (that is, $2 + 1/4 + 1/8$), and its multiple by 7 ($16 + 1/2 + 1/8$) becomes the required answer. This type of procedure (sometimes called the method of "false position" or "false assumption") is familiar in many other arithmetic traditions (*e.g.*, the Chinese, Hindu, Muslim, and Renaissance European), although they appear to have no direct link to the Egyptian.

Geometry. The geometric problems in the papyri seek measurements of figures, like rectangles and triangles of given base and height, by means of suitable arithmetic operations. In a more complicated problem, a rectangle is sought whose area is 12 and whose height is $1/2 + 1/4$ times its base (Golenishchev Papyrus, problem 6). To solve the problem, the ratio is inverted and multiplied by the area, yielding 16; the square root of the result (4) is the base of the rectangle, and $1/2 + 1/4$ times 4, or 3, is the height. The entire process is analogous to the process of solving the algebraic equation for the problem $(x \times 3/4\, x = 12)$, though without the use of a letter for the unknown. An interesting procedure is used to find the area of the circle (Rhind Papyrus, problem 50): $1/9$ of the diameter is discarded and the result is squared. For example, if the diameter is 9, the area is set equal to 64. The scribe recognized that the area of a circle is proportional to the square of the diameter and assumed for the constant of proportionality (that is, $\pi/4$) the value $64/81$. This is a rather good estimate, being about $6/10$ of 1 percent too large. (It is not as close, however, as the now common estimate of $3\,1/7$, first proposed by Archimedes, which is only about $4/100$ of 1 percent too large.) But there is nothing in the papyrus indicating that the scribes were aware that this rule was only approximate rather than exact.

A remarkable result is the rule for the volume of the truncated pyramid (Golenishchev Papyrus, problem 14). The scribe assumes the height to be 6, the base to be a square of side 4, and the top a square of side 2. He multiplies one-third the height times 28, finding the volume to be 56; here, 28 is computed from $2 \times 2 + 2 \times 4 + 4 \times 4$. Since this is correct it can be assumed that the scribe also knew the general rule: $A = (h/3)(a^2 + ab + b^2)$. How the scribes actually derived the rule is a matter for debate, but it is reasonable to suppose that they were aware of related rules, such as that for the volume of a pyramid: one-third the height times the area of the base.

Measurement of distances

The Egyptians employed the equivalent of similar triangles to measure distances. For instance, the *seked* of a pyramid is stated as the number of palms in the horizontal corresponding to a rise of one cubit (seven palms). Thus, if the *seked* is $5\,1/4$ and the base is 140 cubits, the height becomes $93\,1/3$ (Rhind Papyrus, problem 57). The Greek sage Thales of Miletus (6th century BC) is said to have measured the height of pyramids by means of their shadows (the report derives from Hieronymus, a disciple of Aristotle in the 4th century BC). In light of the *seked* computations, however, this report must indicate an aspect of Egyptian surveying that extended back at least 1,000 years before the time of Thales.

Assessment of Egyptian mathematics. The papyri thus bear witness to a mathematical tradition closely tied to the practical accounting and surveying activities of the scribes. Occasionally, the scribes loosened up a bit: one problem (Rhind Papyrus, problem 79), for example, seeks the total from seven houses, seven cats per house, seven mice per cat, seven ears of wheat per mouse, and seven *hekat* of grain per ear (result: 19,607). The underlying scenario can only be guessed at, but it is probably of the playful "As I was going to St. Ives" type—certainly, the scribe's interest in progressions (for which he appears to have a rule) goes beyond practical considerations. Other than this, however, Egyptian mathematics falls firmly within the range of practice.

Even allowing for the scantiness of the documentation that survives, the Egyptian achievement in mathematics must be viewed as modest. Its most striking features are competence and continuity. The scribes managed to work out the basic arithmetic and geometry necessary for their official duties as civil managers, and their methods persisted with little evident change for at least a millennium, perhaps two. Indeed, when Egypt came under Greek domination in the Hellenistic period (from the 3rd century BC onward), the older school methods continued. Quite remarkably, for example, the older unit-fraction methods are still prominent in Egyptian school papyri, written in the demotic (Egyptian) and Greek languages as late as the 7th century AD.

To the extent that Egyptian mathematics left a legacy at all, it was through its impact on the emerging Greek mathematical tradition between the 6th and 4th centuries BC. Because the documentation from this period is limited, the manner and significance of the influence can only be conjectured. But the report about Thales is only one of several such accounts of Greek intellectuals learning from Egyptians; Herodotus and Plato describe with approval Egyptian practices in the teaching and application of mathematics. This literary evidence has historical support, since the Greeks maintained continuous trade and military operations in Egypt from the 7th century BC onward. It is thus plausible that basic precedents for the Greeks' earliest mathematical efforts—how they dealt with fractional parts or measured areas and volumes, or their use of ratios in connection with similar figures—came from the learning of the ancient Egyptian scribes.

Influence on Greek mathematics

Greek mathematics

THE DEVELOPMENT OF PURE MATHEMATICS

The pre-Euclidean period. The Greeks divided the field of mathematics into arithmetic (the study of "multitude," or discrete quantity) and geometry (that of "magnitude," or continuous quantity) and considered both to have originated in practical activities. Proclus, in his *Commentary on Euclid,* observes that geometry, literally, "measurement of land," first arose in surveying practices among the ancient Egyptians, for the flooding of the Nile compelled them each year to redefine the boundaries of properties. Similarly, arithmetic started with the commerce and trade of Phoenician merchants. Although Proclus wrote quite late in the ancient period (in the 5th century AD), his account drew upon views proposed much earlier, by Herodotus (mid-5th century BC), for example, and by Eudemus, a disciple of Aristotle (late 4th century BC).

However plausible, this view is difficult to check, for there is only meagre evidence of practical mathematics from the early Greek period (roughly, the 8th through the 4th centuries BC). Inscriptions on stone, for example, reveal use of a numeral system the same in principle as the familiar Roman numerals. Herodotus seems to have known of the abacus as an aid for computation by both Greeks and Egyptians, and about a dozen stone specimens of Greek abaci survive from the 5th and 4th centuries BC. In the surveying of new cities in the Greek colonies of the 6th and 5th centuries, there was regular use of a standard length of 70 *plethra* (one *plethron* equals 100 feet) as the diagonal of a square of side 50 *plethra;* in fact, the actual diagonal of the square is $50\sqrt{2}$ *plethra,* so this was equivalent to using $^7/_5$ (or 1.4) as an estimate for $\sqrt{2}$, which is now known to equal 1.414.... In the 6th century BC the engineer Eupalinus of Megara directed an aqueduct through a mountain on the island of Samos, and historians still debate how he did it. In a further indication of the practical aspects of early Greek mathematics, Plato describes in his *Laws* how the Egyptians drilled their children in practical problems in arithmetic and geometry; he clearly considered this a model for the Greeks to imitate.

Such hints about the nature of early Greek practical mathematics are confirmed in later sources, for example, in the arithmetic problems in papyrus texts from Ptolemaic Egypt (from the 3rd century BC onward) and the geometric manuals by Hero of Alexandria (1st century AD). In its basic manner this Greek tradition was much like the earlier traditions in Egypt and Mesopotamia. Indeed, it is likely that the Greeks borrowed from such older sources to some extent.

What was distinctive of the Greeks' contribution to mathematics—and what in effect made them the creators of "mathematics," as the term is usually understood—was its development as a theoretical discipline. This means two things: mathematical statements are general, and they are confirmed by proof. For example, the Mesopotamians had procedures for finding whole numbers *a, b,* and *c* for which $a^2 + b^2 = c^2$ (*e.g.,* 3, 4, 5; 5, 12, 13; or 119, 120, 169). From the Greeks came a proof of a general rule for finding all such sets of numbers (now called Pythagorean triples): if one takes any whole numbers p and q, both being even or both odd, then $a = (p^2 - q^2)/2$, $b = pq$, and $c = (p^2 + q^2)/2$. As Euclid proves in Book X of the *Elements,* numbers of this form satisfy the relation for Pythagorean triples. Further, the Mesopotamians appear to have understood that sets of such numbers *a, b,* and *c* form the sides of right triangles, but the Greeks proved this result (Euclid, in fact, proves it twice, in *Elements,* Book I, proposition 47, and in a more general form in *Elements,* Book VI, proposition 31), and these proofs occur in the context of a systematic presentation of the properties of plane geometric figures.

Pythagorean triples

The *Elements,* composed by Euclid of Alexandria, around 300 BC, was the pivotal contribution to theoretical geometry, but the transition from practical to theoretical mathematics had occurred much earlier, sometime in the 5th century BC. Initiated by men like Pythagoras of Samos (late 6th century) and Hippocrates of Chios (late 5th century), the theoretical form of geometry was advanced by others, most prominently the Pythagorean Archytas of Tarentum, Theaetetus of Athens, and Eudoxus of Cnidus (4th century). Because the actual writings of these men do not survive, knowledge about their work depends on remarks made by later writers. While even this limited evidence reveals how heavily Euclid depended on them, it does not set out clearly the motives behind their studies.

It is thus a matter of debate how and why this theoretical transition took place. A frequently cited factor is the discovery of the irrational. The early Pythagoreans held that "all things are number." This might be taken to mean that any geometric measure can be associated with some number (that is, some whole number or fraction; in modern terminology, rational number), for in Greek usage the term for number, *arithmos,* refers exclusively to whole numbers or, in some contexts, to ordinary fractions. This assumption is common enough in practice, as when the length of a given line is said to be so many feet plus a fractional part. However, it breaks down for the lines that form the side and diagonal of the square. (For example, if it is supposed that the ratio between the side and diagonal may be expressed as the ratio of two whole numbers, it can be shown that both of these numbers must be even. This is impossible, since every fraction may be expressed as a ratio of two whole numbers having no common factors.) Geometrically, this means that there is no length that could serve as a unit of measure of both the side and diagonal; that is, the side and diagonal cannot each equal the same length multiplied by (different) whole numbers. Accordingly, the Greeks called such pairs of lengths "incommensurable." (In modern terminology, unlike that of the Greeks, the term "number" is applied to such quantities as $\sqrt{2}$, but they are called irrational.)

This result was already well known at the time of Plato and may well have been discovered within the school of Pythagoras in the 5th century BC, as some late authorities like Pappus of Alexandria (4th century AD) maintain. In any case, by 400 BC it was known that lines corresponding to $\sqrt{3}$, $\sqrt{5}$, and other square roots are incommensurable with a fixed unit length. The more general result, the geometric equivalent of the theorem that $\sqrt{p}$ is irrational whenever p is not a rational square number, is associated with Plato's friend Theaetetus. Both Theaetetus and Eudoxus contributed to the further study of irrationals, and their followers collected the results into a substantial theory, as represented by the 115 propositions of Book X of the *Elements*.

The theory of irrationals

The discovery of irrationals must have affected the very nature of early mathematical research, for it made clear that arithmetic was insufficient for the purposes of geometry, despite the assumptions made in practical work. Further, once such seemingly obvious assumptions as the commensurability of all lines turned out to be, in fact, false, then in principle all mathematical assumptions were rendered suspect. At the least, it became necessary to justify carefully all claims made about mathematics. Even more basically, it became necessary to establish what a reasoning has to be like to qualify as a proof. Apparently, Hippocrates of Chios, in the 5th century BC, and others soon after him had already begun the work of organizing geometric results into a systematic form in textbooks called "elements" (meaning "fundamental results" of geometry). These were to serve as sources for Euclid in his comprehensive textbook a century later.

The early mathematicians were not an isolated group but part of a larger, intensely competitive intellectual environment of pre-Socratic thinkers in Ionia and Italy, as well as Sophists at Athens. By insisting that only permanent things could have real existence, the philosopher Parmenides (5th century BC) called into question the most basic claims about knowledge itself. In contrast, Heracleitus (*c.* 500 BC) maintained that all permanence is an illusion, for the things that are perceived arise through a subtle balance of opposing tensions. What is meant by "knowledge" and "proof" thus came into debate.

Mathematical issues were often drawn into these debates. For some, like the Pythagoreans (and, later, Plato), the certainty of mathematics was held as a model for reasoning in other areas, like politics and ethics. But for others, mathematics seemed prone to contradiction. Zeno of Elea (5th century BC) posed paradoxes about quantity and motion. In one such paradox, it is assumed that a line can be bisected again and again without limit; if the division ultimately results in a set of points of zero length, then even infinitely many of them sum up only to zero, but, if it results in tiny line segments, then their sum will be infinite. In effect, the length of the given line must be both zero and infinite. In the 5th century BC a solution of such paradoxes was attempted by Democritus and the "atomists," philosophers who held that all material bodies are ultimately made up of invisibly small "atoms" (the Greek word *atomon* means "indivisible"). But in geometry such a view came into conflict with the existence of incommensurable lines, since the atoms would become the measuring units of all lines, even incommensurable ones. Protagoras and Democritus puzzled over whether the tangent to a circle meets it at a point or a line. The Sophists Antiphon and Bryson (both 5th century BC) considered how to compare the circle to polygons inscribed in it.

Influence of the pre-Socratics

The pre-Socratics thus revealed difficulties in specific assumptions about the infinitely many and the infinitely small, about the relation of geometry to physical reality, as well as in more general conceptions like "existence" and "proof." Philosophical questions such as these need not have affected the technical researches of mathematicians, but they did make them aware of difficulties that could bear on fundamental matters and so made them the more cautious in defining their subject matter.

Any such review of the possible effects of factors such as these is purely conjectural, since the sources are fragmentary and never make explicit how the mathematicians responded to the issues that were raised. But it is the particular concern over fundamental assumptions and proofs that distinguishes Greek mathematics from the earlier traditions. Plausible factors behind this concern can be identified in the special circumstances of the early Greek tradition—its technical discoveries and its cultural environment—even if it is not possible to describe in detail how these changes took place.

The Elements. The principal source for reconstructing pre-Euclidean mathematics is Euclid's *Elements*, for the major part of its contents can be traced back to research from the 4th century BC and in some cases even earlier. The first four books present constructions and proofs of plane geometric figures: Book I deals with the congruence of triangles, the properties of parallel lines, and the area relations of triangles and parallelograms; Book II establishes equalities relating to squares, rectangles, and triangles; Book III covers basic properties of circles; and Book IV sets out constructions of polygons in circles. Much of the content of Books I–III was already familiar to Hippocrates, and the material of Book IV can be associated with the Pythagoreans, so that this portion of the *Elements* has roots in 5th-century research. It is known, however, that questions about parallels were debated in Aristotle's school (around 350 BC), and so it may be assumed that efforts to prove results—such as the theorem stating that, for any given line and given point, there always exists a unique line through that point and parallel to the line—were tried and failed. Thus, the decision to found the theory of parallels on a postulate, as in Book I of the *Elements*, must have been a relatively recent development in Euclid's time. (The postulate would later become the subject of much study, and in modern times it led to the discovery of the so-called non-Euclidean geometries.)

Book V sets out a general theory of proportion, that is, a theory that does not require any restriction to commensurable magnitudes. This general theory derives from Eudoxus. On the basis of the theory, Book VI describes the properties of similar plane rectilinear figures and so generalizes the congruence theory of Book I. It appears that the technique of similar figures was already known in the 5th century BC, even though a fully valid justification could not have been given before Eudoxus worked out his theory of proportion.

The theory of numbers

Books VII–IX deal with what the Greeks called "arithmetic," the theory of whole numbers. It includes the properties of numerical proportions, greatest common divisors, least common multiples, and relative primes (Book VII); propositions on numerical progressions and square and cube numbers (Book VIII); and special results, like unique factorization into primes, the existence of an unlimited number of primes, and the formation of "perfect" numbers, that is, those numbers that equal the sum of their proper divisors (Book IX). In some form, Book VII stems from Theaetetus and Book VIII from Archytas.

Book X presents a theory of irrational lines and derives from the work of Theaetetus and Eudoxus. The remaining books treat the geometry of solids. Book XI sets out results on solid figures analogous to those for planes in Books I and VI; Book XII proves theorems on the ratios of circles, the ratios of spheres, and the volumes of pyramids and cones; Book XIII shows how to inscribe the five regular solids in a given sphere (compare the constructions of plane figures in Book IV). The measurement of curved figures in Book XII is inferred from that of rectilinear figures; for a particular curved figure a sequence of rectilinear figures is considered in which succeeding figures in the sequence become continually closer to the curved figure; the particular method used by Euclid derives from Eudoxus. The solid constructions in Book XIII derive from Theaetetus.

In sum the *Elements* gathered together the whole field of elementary geometry and arithmetic that had developed in the two centuries before Euclid. Doubtless, Euclid must be credited with particular aspects of this work, certainly with its editing as a comprehensive whole. But it is not possible to identify for certain even a single one of its results as having been his discovery. Other more advanced fields, though not touched on in the *Elements*, were already being vigorously studied in Euclid's time, in some

cases by Euclid himself. For these fields his textbook, true to its name, provides the appropriate "elementary" introduction.

One such field is the study of geometric constructions. Euclid, like geometers in the generation before him, divided mathematical propositions into two kinds: "theorems" and "problems." A theorem makes the claim that all terms of a certain description have a specified property; a problem seeks the construction of a term that is to have a specified property. In the *Elements* all the problems are constructible on the basis of three stated postulates: that a line can be constructed by joining two given points, that a given line segment can be extended in a line indefinitely, and that a circle can be constructed with a given point as centre and a given line segment as radius. These postulates in effect restricted the constructions to the use of the so-called Euclidean tools—*i.e.*, a compass and a straightedge or unmarked ruler.

The Euclidean tools

The three classical problems. Although Euclid solves more than 100 construction problems in the *Elements*, many more were posed whose solutions required more than just compass and straightedge. Three such problems stimulated so much interest among later geometers that they have come to be known as the "classical problems": doubling the cube, *i.e.*, constructing a cube whose volume is twice that of a given cube; trisecting the angle; and squaring the circle. Even in the pre-Euclidean period the effort to construct a square equal in area to a given circle had begun. Some related results came from Hippocrates, others were reported from Antiphon and Bryson, and Euclid's theorem on the circle in *Elements*, Book XII, proposition 2, which states that circles are in the ratio of the squares of their diameters, was important for this search. But the first actual constructions (not, it must be noted, by means of the Euclidean tools, for this is impossible) came only in the 3rd century BC. The early history of angle trisection is obscure. Presumably it was attempted in the pre-Euclidean period, although solutions are known only from the 3rd century or later.

There are several successful efforts at doubling the cube, however, that date from the pre-Euclidean period. Hippocrates showed that the problem could be reduced to that of finding two mean proportionals: if for a given line a it is necessary to find x such that $x^3 = 2a^3$, lines x and y may be sought such that $a:x = x:y = y:2a$; for then $a^3/x^3 = (a/x)^3 = (a/x)(x/y)(y/2a) = a/2a = 1/2$. (Note that the same argument holds for any multiplier, not just the number 2.) Thus, the cube can be doubled if it is possible to find the two mean proportionals x and y between the two given lines a and $2a$. Constructions of the problem of the two means were proposed by Archytas, Eudoxus, and Menaechmus in the 4th century BC. Menaechmus, for example, constructed three curves corresponding to these same proportions: $x^2 = ay$, $y^2 = 2ax$, and $xy = 2a^2$; the intersection of any two of them then produces the line x that solves the problem. Menaechmus' curves are conic sections: the first two are parabolas, the third a hyperbola. Thus, it is often claimed that Menaechmus originated the study of the conic sections. Indeed, Proclus and his older authority, Geminus (mid-1st century AD), appear to have held this view. The evidence does not indicate how Menaechmus actually conceived of the curves, however, so it is possible that the formal study of the conic sections as such did not begin until later, near the time of Euclid. Both Euclid and an older contemporary, Aristaeus, composed treatments (now lost) of the theory of conic sections.

In seeking the solutions of problems, geometers developed a special technique, which they called "analysis." They assumed the problem to have been solved and then, by investigating the properties of this solution, worked back to find an equivalent problem that could be solved on the basis of the givens. To obtain the formally correct solution of the original problem, then, geometers reversed the procedure: first the data were used to solve the equivalent problem derived in the analysis, and from the solution obtained the original problem was then solved. In contrast to analysis, this reversed procedure is called "synthesis."

Analysis and synthesis

Menaechmus' cube duplication is an example of analysis: he assumed the mean proportionals x and y and then discovered them to be equivalent to the result of intersecting the three curves whose construction he could take as known. (The synthesis consists of introducing the curves, finding their intersection, and showing that this solves the problem.) It is clear that geometers of the 4th century BC were well acquainted with this method, but Euclid provides only syntheses, never analyses, of the problems solved in the *Elements*. Certainly in the cases of the more complicated constructions, however, there can be little doubt that some form of analysis preceded the syntheses presented in the *Elements*.

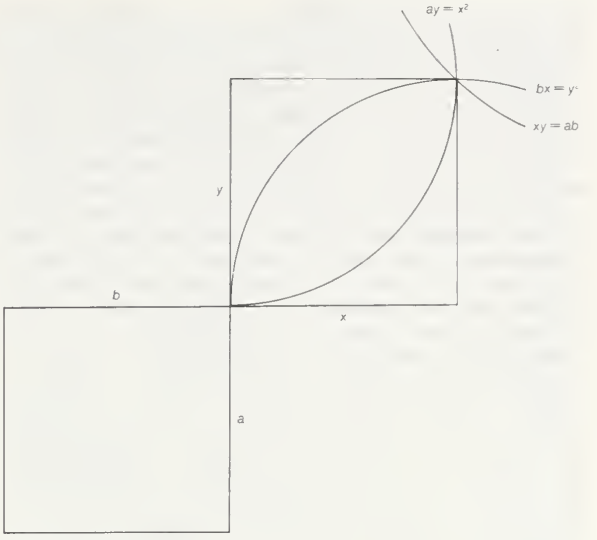

Figure 2: Cube duplication.

GEOMETRY IN THE 3RD CENTURY BC

The *Elements* was one of several major efforts by Euclid and others to consolidate the advances made over the 4th century BC. On the basis of these advances, Greek geometry entered its golden age in the 3rd century. This was a period rich with geometric discoveries, particularly in the solution of problems by analysis and other methods, and was dominated by the achievements of two figures: Archimedes of Syracuse (b. early 3rd century–d. 212 BC) and Apollonius of Perga (mid-3rd to early 2nd century BC).

Archimedes. Archimedes was most noted for his use of the Eudoxean method of exhaustion in the measurement of curved surfaces and volumes and for his applications of geometry to mechanics. To him is owed the first appearance and proof of the approximation $3\frac{1}{7}$ for the ratio of the circumference to the diameter of the circle (what is now designated π). Characteristically, Archimedes went beyond familiar notions, such as that of simple approximation, to more subtle insights, like the notion of bounds. For example, he showed that the perimeters of regular polygons circumscribed about the circle eventually become less than $3\frac{1}{7}$ the diameter as the number of their sides increases (Archimedes established the result for 96-sided polygons); similarly, the perimeters of the inscribed polygons eventually become greater than $3\frac{10}{71}$. Thus, these two values are upper and lower bounds, respectively, of π.

Archimedes' result bears on the problem of circle quadrature in the light of another theorem he proved: that the area of a circle equals the area of a triangle whose height equals the radius of the circle and whose base equals its circumference. He established analogous results for the sphere showing that the volume of a sphere is equal to that of a cone whose height equals the radius of the sphere and whose base equals its surface area; the surface area of the sphere he found to be four times the area of its greatest circle. Equivalently, the volume of a sphere is shown to be two-thirds that of the cylinder which just contains it (that is, having height and diameter equal to the diameter of the sphere), while its surface is also equal to two-thirds that of the same cylinder (that is, if the circles that enclose the cylinder at top and bottom are included). The Greek historian Plutarch (early 2nd century AD) relates that Archimedes requested the figure for this theorem to

Volume of the sphere

be engraved on his tombstone, which is confirmed by the Roman writer Cicero (1st century BC), who actually located the tomb when he was quaestor of Sicily in 75 BC.

Apollonius. The work of Apollonius of Perga extended the field of geometric constructions far beyond the range in the *Elements*. For example, Euclid in Book III shows how to draw a circle so as to pass through three given points or to be tangent to three given lines; Apollonius (in a work called *Tangencies*, which no longer survives) found the circle tangent to three given circles, or tangent to any combination of three points, lines, and circles. (The three-circle tangency construction, one of the most extensively studied geometric problems, has attracted more than 100 different solutions in the modern period.)

Apollonius is best known for his *Conics*, a treatise in eight books (Books I–IV survive in Greek, V–VII in a medieval Arabic translation; Book VIII is lost). The conic sections are the curves formed when a plane intersects the surface of a cone (or double cone); it is assumed that the surface of the cone is generated by the rotation of a line through a fixed point around the circumference of a circle which is in a plane not containing that point. (The fixed point is the vertex of the cone, and the rotated line its generator.) There are three basic types: if the cutting plane is parallel to one of the positions of the generator, it produces the "parabola"; if it meets the cone only on one side of the vertex, it produces an "ellipse" (of which the circle is a special case), but, if it meets both parts of the cone, a "hyperbola." Apollonius sets out in detail the properties of these curves. He shows, for example, that for given line segments a and b the parabola corresponds to the relation (in modern notation) $y^2 = ax$, the ellipse to $y^2 = ax - ax^2/b$, and the hyperbola to $y^2 = ax + ax^2/b$.

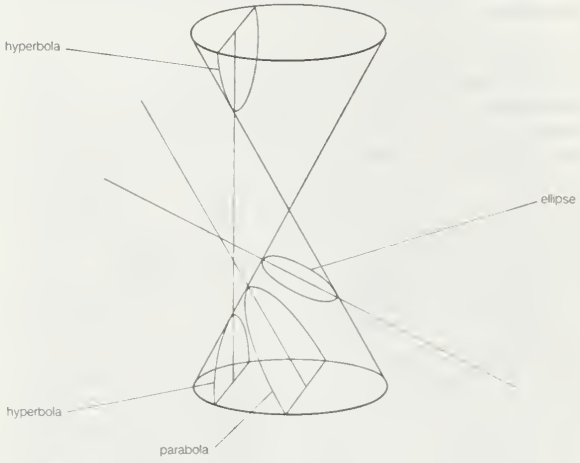

Figure 3: Conic sections.

Apollonius' treatise on conics in part consolidated more than a century of work before him and in part presented new findings of his own. As mentioned above, Euclid had already issued a textbook on the conics, while even earlier Menaechmus had played a role in their study. The names that Apollonius chose for the curves (the terms may be original with him) indicate yet an earlier connection. In the pre-Euclidean geometry *parabolē* referred to a specific operation, the "application" of a given area to a given line, in which the line x is sought such that $ax = b^2$ (where a and b are given lines); alternatively, x may be sought such that $x(a + x) = b^2$, or $x(a - x) = b^2$, and in these cases the application is said to be in "excess" (*hyperbolē*) or "defect" (*elleipsis*) by the amount of a square figure (namely, x^2). These constructions, which amount to a geometric solution of the general quadratic, appear in Books I, II, and VI of the *Elements* and can be associated in some form with the 5th-century Pythagoreans.

The *Conics*

Apollonius presented a comprehensive survey of the properties of these curves. A sample of the topics he covered includes the following: the relations satisfied by the diameters and tangents of conics (Book I); how hyperbolas are related to their "asymptotes," the lines they approach without ever meeting (Book II); how to draw tangents to given conics (Book II); relations of chords intersecting in conics (Book III); the determination of the number of ways in which conics may intersect (Book IV); how to draw "normal" lines to conics, that is, lines meeting them at right angles (Book V); and the congruence and similarity of conics (Book VI).

By Apollonius' explicit statement, his results are of principal use as methods for the solution of geometric problems via conics. While he actually solved only a limited set of problems, the solutions of many others can be inferred from his theorems. For instance, the theorems of Book III permit the determination of conics that pass through given points or are tangent to given lines. In another work (now lost) Apollonius solved the problem of cube duplication by conics (a solution related in some way to that given by Menaechmus); further, a solution of the problem of angle trisection given by Pappus may have come from Apollonius or have been influenced by his work.

With the advance of the field of geometric problems by Euclid, Apollonius, and their followers, it became appropriate to introduce a classifying scheme: those problems solvable by means of conics were called solid, while those solvable by means of circles and lines only (as assumed in Euclid's *Elements*) were called planar. Thus, one can double the square by planar means (as in *Elements*, Book II, proposition 14), but one cannot double the cube in such a way, although a solid construction is possible (as given above). Similarly, the bisection of any angle is a planar construction (as shown in *Elements*, Book I, proposition 9), but the general trisection of the angle is of the solid type. It is not known when the classification was first introduced or when the planar methods were assigned canonical status relative to the others, but it seems plausible to date this near Apollonius' time. Indeed, much of his work—books like the *Tangencies*, the *Vergings* (or *Inclinations*), and the *Plane Loci*, now lost but amply described by Pappus—turns on the project of setting out the domain of planar constructions in relation to solutions by other means. On the basis of the principles of Greek geometry it cannot be demonstrated, however, that it is impossible to effect by planar means certain solid constructions (like the cube duplication and angle trisection). These results were only established by algebraists in the 19th century (notably by the French mathematician Pierre Laurent Wantzel in 1837).

Linear problems

A third class of problems, called linear, embraced those solvable by means of curves other than the circle and the conics (in Greek, the word for "line," *grammē*, refers to all lines, whether curved or straight). For instance, one group of curves, the conchoids (from the Greek word for shell), are formed by marking off a certain length on a ruler and then pivoting it about a fixed point in such a way that one of the marked points stays on a given line; the other marked point traces out a conchoid. These curves can be used wherever a solution involves the positioning of a marked ruler relative to a given line (in Greek, such constructions are called *neuses*, or "vergings" of a line to a given point). For example, any acute angle (figured as

Figure 4: *Conchoid curve.*
From fixed point *P*, several lines are drawn. A standard distance (*a*) is marked along each line from line *LN*, and the connection of the points creates a conchoid curve.

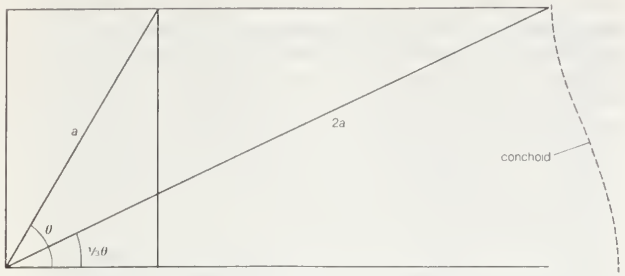

Figure 5: Angle trisection by means of a conchoid.

the angle between one side and the diagonal of a rectangle) can be trisected by taking a length equal to twice the diagonal and moving it about until it comes to be inserted between two other sides of the rectangle. If, instead, the appropriate conchoid relative to either of those sides is introduced, the required position of the line can be determined without the trial and error of a moving ruler. Because the same construction can be effected by means of a hyperbola, however, the problem is not linear but solid. Such uses of the conchoids were presented by Nicomedes (middle or late 3rd century BC), and their replacement by equivalent solid constructions appears to have come soon after, perhaps by Apollonius or his associates.

Some of the curves used for problem solving are not so reducible. For example, the Archimedean spiral couples uniform motion of a point on a half ray with uniform rotation of the ray around a fixed point at its end. Such curves have their principal interest as means for squaring the circle and trisecting the angle.

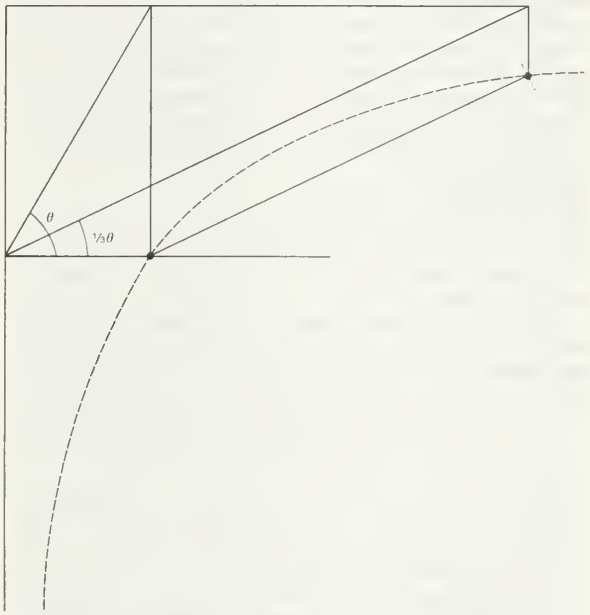

Figure 6: Angle trisection by means of a hyperbola.

Applied geometry. A major activity among geometers in the 3rd century BC was the development of geometric approaches in the study of the physical sciences, specifically, optics, mechanics, and astronomy. In each case the aim was to formulate the basic concepts and principles in terms of geometric and numerical quantities and then to derive the fundamental phenomena of the field by geometric constructions and proofs.

Optics

In optics, Euclid's textbook (called the *Optics*) set the precedent. Euclid postulated visual rays to be straight lines, and he defined the apparent size of an object in terms of the angle formed by the rays drawn from the top and the bottom of the object to the observer's eye. He then proved, for example, that nearer objects appear larger and appear to move faster and showed how to measure the height of distant objects from their shadows or reflected images, and so on. Other textbooks set out theorems on the phenomena of reflection and refraction (the field called catoptrics). The most extensive survey of optical phenomena is a treatise attributed to the astronomer Ptolemy (2nd century AD), which survives only in the form of an incomplete Latin translation (12th century) based on a lost Arabic translation. It covers the fields of geometric optics and catoptrics, as well as experimental areas, such as binocular vision, and more general philosophical principles (the nature of light, vision, and colour). Of a somewhat different sort are the studies of burning mirrors by Diocles (late 2nd century BC), who proved that the surface that reflects the rays from the Sun to a single point is a paraboloid of revolution. Constructions of such devices remained of interest as late as the 6th century AD, when Anthemius of Tralles, best known for his work as architect of the Hagia Sophia at Constantinople, compiled a survey of remarkable mirror configurations.

Mechanics was dominated by the work of Archimedes, who was the first to prove the principle of balance: that two weights are in equilibrium when they are inversely proportional to their distances from the fulcrum. From this principle he developed a theory of the centres of gravity of plane and solid figures. He was also the first to state and prove the principle of buoyancy—that floating bodies displace their equal in weight—and to use it for proving the conditions of stability of segments of spheres and paraboloids, solids formed by rotating a parabolic segment about its axis. Archimedes proved the conditions under which this solid will return to its initial position if tipped, in particular, for the positions now called "stable I" and "stable II," where the vertex faces up and down, respectively.

In his work *Method Concerning Mechanical Theorems*, Archimedes also set out a special "mechanical method" that he used for the discovery of results on volumes and centres of gravity. He employed the bold notion of constituting solids from the plane figures formed as their sections (*e.g.*, the circles that are the plane sections of spheres, cones, cylinders, and other solids of revolution), assigning to such figures a weight proportional to their area. For example, to measure the volume of a sphere, he imagined a balance beam, one of whose arms is a diameter of the sphere with the fulcrum at one endpoint of this diameter and the other arm an extension of the diameter to the other side of the fulcrum by a length equal to the diameter. Archimedes showed that the three circular cross sections made by a plane cutting the sphere and the associated cone and cylinder will be in balance (the circle in the cylinder with the circles in the sphere and cone) if the circle in the cylinder is kept in its original place, while the circles in the sphere and cone are placed with their centres of gravity at the opposite end of the balance. Doing this for all the sets of circles formed as cross sections of these solids by planes, he concluded that the solids themselves are in balance, the cylinder with the sphere and the cone together if the cylinder is left where it is, while the sphere and cone are placed with their centres of gravity at the opposite end of the balance. Since the centre of gravity of the cylinder is the midpoint of its axis, it follows that (*sphere* + *cone*):*cylinder* = 1:2 (by the inverse proportion of weights and distances). Since the volume of the cone is one-third that of the cylinder, however, the volume of the sphere is found to be one-sixth that of the cylinder. In similar manner, Archimedes worked out the volumes and centres of gravity of spherical segments and segments of the solids of revolution of conic sections (paraboloids, ellipsoids, and hyperboloids). The critical notions—constituting solids out of their plane sections and assigning weights to geometric figures—were not formally valid within the standard conceptions of Greek geometry.

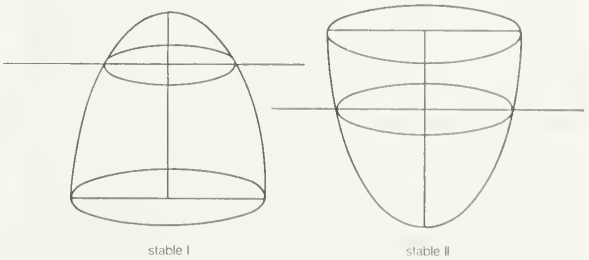

Figure 7: Paraboloids.

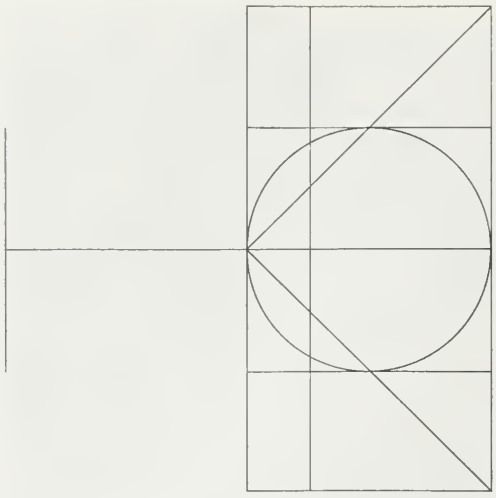

Figure 8: Measurement of the sphere.

and Archimedes admitted this. But he maintained that, although his arguments were not "demonstrations" (*i.e.*, proofs), they had value for the discovery of results about these figures.

Astronomy

The geometric study of astronomy has pre-Euclidean roots, with Eudoxus having developed a model for planetary motions around a stationary Earth. Accepting the principle—which, according to Eudemus, was first proposed by Plato—that only combinations of uniform circular motions are to be used, Eudoxus represented the path of a planet as the result of superimposing rotations of three or more concentric spheres whose axes are set at different angles. Although the fit with the phenomena was unsatisfactory, the curves thus generated (the *hippopede*, or "horse-fetter") continued to be of interest for their geometric properties, as is known through remarks by Proclus. Later geometers continued the search for geometric patterns satisfying the Platonic conditions. The simplest model, a scheme of circular orbits centred on the Sun, was introduced by Aristarchus of Samos (3rd century BC), but this was rejected by others, since a moving Earth was judged to be impossible on physical grounds. But Aristarchus' scheme could have suggested use of an "eccentric" model, in which the planets rotate about the Sun and the Sun in turn rotates about the Earth. Apollonius introduced an alternative "epicyclic" model, in which the planet turns about a point that itself orbits in a circle (the "deferent") centred at or near the Earth. As Apollonius knew, his epicyclic model is geometrically equivalent to an eccentric. These models were well adapted for explaining other phenomena of planetary motion. For instance, if the Earth is displaced from the centre of a circular orbit (as in the eccentric scheme), the orbiting body will appear to vary in speed (appearing faster when nearer the observer, slower when farther away), as is in fact observed for the Sun, Moon, and planets. By varying the relative sizes and rotation rates of the epicycle and deferent, in combination with the eccentric, a flexible device may be obtained for representing planetary motion.

LATER TRENDS IN GEOMETRY AND ARITHMETIC

Greek trigonometry and mensuration. After the 3rd century BC, mathematical research shifted increasingly away from the pure forms of constructive geometry toward areas related to the applied disciplines, in particular to astronomy. The necessary theorems on the geometry of the sphere (called spherics) were compiled into textbooks, such as the one by Theodosius (3rd or 2nd century BC), that consolidated the earlier work by Euclid and the work of Autolycus of Pitane (fl. *c.* 300 BC) on spherical astronomy. More significantly, in the 2nd century BC the Greeks first came into contact with the fully developed Mesopotamian astronomical systems and took from them many of their observations and parameters (for example, values for the average periods of astronomical phenomena). While retaining their own commitment to geometric models rather than adopting the arithmetic schemes of the Mesopotamians, the Greeks, nevertheless, followed the Mesopotamians' lead in seeking a predictive astronomy based on a combination of mathematical theory and observational parameters. They thus made it their goal not merely to describe but to calculate the angular positions of the planets on the basis of the numerical and geometric content of the theory. This major restructuring of Greek astronomy, in both its theoretical and practical respects, was due primarily to Hipparchus (2nd century BC), whose work was consolidated and further advanced by Ptolemy.

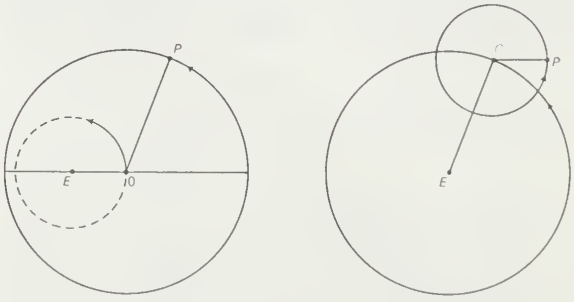

Figure 9: Eccentric and epicycle.

The measurement of angles

To facilitate their astronomical researches, the Greeks developed techniques for the numerical measurement of angles, a precursor of trigonometry, and produced tables suitable for practical computation. Early efforts to measure the numerical ratios in triangles were made by Archimedes and Aristarchus. Their results were soon extended, and comprehensive treatises on the measurement of chords (in effect, a construction of a table of values equivalent to the trigonometric sine) were produced by Hipparchus and by Menelaus of Alexandria (early 2nd century AD). These works are now lost, but the essential theorems and tables are preserved in Ptolemy's *Almagest* (Book 1, chapter 10). For computing with angles, the Greeks adopted the Mesopotamian sexagesimal method in arithmetic, whence it survives in the standard units for angles and time employed to this day.

Number theory. Although Euclid handed down a precedent for number theory in Books VII–IX of the *Elements*, later writers made no further effort to extend the field of theoretical arithmetic in his demonstrative manner. Beginning with Nicomachus of Gerasa (fl. *c.* AD 100), several writers produced collections expounding a much simpler form of number theory. A favourite result is the representation of arithmetic progressions in the form of "polygonal numbers." For instance, if the numbers 1, 2, 3, 4, . . . are added successively, the "triangular" numbers 1, 3, 6, 10, . . . are obtained; similarly, the odd numbers 1, 3, 5, 7, . . . sum to the "square" numbers 1, 4, 9, 16, . . . , while the sequence 1, 4, 7, 10, . . . , with a constant difference of 3, sums to the "pentagonal" numbers 1, 5, 12, 22, ... In general, these results can be expressed in the form of geometric shapes formed by lining up dots in the appropriate two-dimensional configurations. In the ancient arithmetics, such results are invariably presented as particular cases, without any general notational method or general proof. The writers in this tradition are called neo-Pythagoreans, since they viewed themselves as continuing the Pythagorean school of the 5th century BC, and in the spirit of ancient Pythagoreanism they tied their numerical interests to a philosophical theory that was an amalgam of Platonic metaphysical and theological doctrines. With its exponent Iamblichus of Chalcis (4th century AD), neo-Pythagoreans became a prominent part of the revival of pagan religion in opposition to Christianity in late antiquity.

An interesting concept of this school of thought, which Iamblichus attributes to Pythagoras himself, is that of "amicable numbers"; two numbers are amicable if each is equal to the sum of the proper divisors of the other (for example, 220 and 284). Attributing virtues such as friendship and justice to numbers was characteristic of the Pythagoreans at all times.

Diophantus of Alexandria

Of much greater mathematical significance is the arithmetic work of Diophantus of Alexandria (active at an unknown time between the 2nd century BC and the 3rd

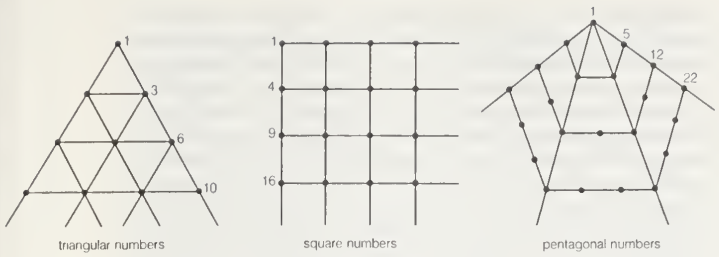

Figure 10: Polygonal arrays.

century AD). His writing, the *Arithmetica,* originally in 13 books (six survive in Greek, another four in the medieval Arabic translation), sets out hundreds of arithmetic problems with their solutions. For example, Book II, problem 8, seeks to express a given square number as the sum of two square numbers (here and throughout, the "numbers" are rational). Like those of the neo-Pythagoreans, his treatments are always of particular cases rather than general solutions; thus, in this problem the given number is taken to be 16 and the solutions worked out are $^{256}/_{25}$ and $^{144}/_{25}$. In this example, as is often the case, the solutions are not unique; indeed, in the very next problem Diophantus shows how a number given as the sum of two squares (*e.g.,* $13 = 4 + 9$) can be expressed differently as the sum of two other squares (for example, $13 = {}^{324}/_{25} + {}^{1}/_{25}$).

To find his solutions, Diophantus adopted an arithmetic form of the method of analysis. He first reformulated the problem in terms of one of the unknowns, and he then manipulated it as if it were known until an explicit value for the unknown emerged. He even adopted an abbreviated notational scheme to facilitate such operations, where, for example, the unknown is symbolized by a figure somewhat resembling the Roman letter *S.* (This is a standard abbreviation for the word number in ancient Greek manuscripts.) Thus, in the first problem discussed above, if S is one of the unknown solutions, then $16 - S^2$ is a square, supposing the other unknown to be $2S - 4$ (where the 2 is arbitrary but the 4 chosen because it is the square root of the given number 16), Diophantus found from summing the two unknowns ($[2S - 4]^2$ and S^2) that $4S^2 - 16S + 16 + S^2 = 16$, or $5S^2 = 16S$, that is, $S = {}^{16}/_{5}$. So one solution is $S^2 = {}^{256}/_{25}$, while the other solution is $16 - S^2$, or $^{144}/_{25}$.

Survival and influence of Greek mathematics. Notable in the closing phase of Greek mathematics were Pappus (early 4th century AD), and Theon (late 4th century) and his daughter Hypatia (d. 415). All were active in Alexandria as professors of mathematics and astronomy, and they produced extensive commentaries on the major authorities—Pappus and Theon on Ptolemy, Hypatia on Diophantus and Apollonius. Later, Eutocius of Ascalon (early 6th century) produced commentaries on Archimedes and Apollonius. While much of their output has since been lost, much survives. They proved themselves reasonably competent in technical matters but little inclined toward significant insights (their aim was usually to fill in minor steps assumed in the proofs, to append alternative proofs, and the like), and the level of originality was very low. But these scholars frequently preserved fragments of older works that are now lost, and their teaching and editorial efforts assured the survival of the works of Euclid, Archimedes, Apollonius, Diophantus, Ptolemy, and others that now do exist, either in Greek manuscripts or in medieval translations (Arabic, Hebrew, and Latin) derived from them.

The legacy of Greek mathematics, particularly in the fields of geometry and geometric science, was enormous. From an early period the Greeks formulated the objectives of mathematics not in terms of practical procedures but as a theoretical discipline committed to the development of general propositions and formal demonstrations. The range and diversity of their findings, especially those of the masters of the 3rd century BC, supplied geometers with subject matter for centuries thereafter, even though the tradition that was transmitted into the Middle Ages and Renaissance was incomplete and defective.

The rapid rise of mathematics in the 17th century was based in part on the conscious imitation of the ancient classics and on competition with them. In the geometric mechanics of Galileo and the infinitesimal researches of Kepler and Cavalieri, it is possible to perceive a direct inspiration from Archimedes. The study of the advanced geometry of Apollonius and Pappus stimulated new approaches in geometry—for example, the analytic methods of Descartes and the projective theory of Girard Desargues. Purists like Huygens and Newton insisted on the Greek geometric style as a model of rigour, just as others sought to escape its forbidding demands of completely worked-out proofs. The full impact of Diophantus' work is evident particularly with Pierre de Fermat in his researches in algebra and number theory. Although mathematics has today gone far beyond the ancient achievements, the leading figures of antiquity, like Archimedes, Apollonius, and Ptolemy, can still be rewarding reading for the ingenuity of their insights. (W.R.K.)

Mathematics in medieval Islām

Origins. In Hellenistic times and in late antiquity, scientific learning in the eastern part of the Roman world was spread over a variety of centres, and Justinian's closing of the pagan academies in Athens in 529 gave further impetus to this diffusion. An additional factor was the translation and study of Greek scientific and philosophical texts sponsored both by monastic centres of the various Christian churches in the Levant, Egypt, and Mesopotamia and by enlightened rulers of the Sāsanian dynasty in places like the medical school at Gondeshapur.

Indian astronomy and mathematics

Also important were developments in India in the first few centuries AD. Although the decimal system for whole numbers was apparently not known to the Indian astronomer Āryabhaṭa I (b. 476), it was used by his pupil Bhāskara I in 620, and by 670 the system had reached northern Mesopotamia, where the Nestorian bishop Severus Sebokht praised its Hindu inventors as discoverers of things more ingenious than those of the Greeks. Earlier, in the late 4th or early 5th century, the anonymous Hindu author of an astronomical handbook, the *Sūrya Siddhānta,* had tabulated the sine function (unknown in Greece) for every $3\frac{3}{4}°$ of arc from $3\frac{3}{4}°$ to 90°.

Within this intellectual context the rapid expansion of Islām took place between the time of Muḥammad's return to Mecca from his exile in Medina in 630 and the Muslim conquest of lands extending from Spain to the borders of China by 715. Not long afterward, Muslims began the acquisition of foreign learning, and, by the time of the caliph al-Manṣūr (d. 775), such Indian and Persian astronomical material as the *Brāhma-sphuṭa-siddhānta* and the *Shāh's Tables* had been translated into Arabic. The subsequent acquisition of Greek material was greatly advanced when the caliph al-Ma'mūn constructed a translation and research centre, the House of Wisdom, in Baghdad during his reign (813–833). Most of the translations were done from Greek and Syriac by Christian scholars, but the impetus and support for this activity came from Muslim patrons. These included not only the caliph but also wealthy individuals such as the three brothers known as the Banū Mūsā, whose treatises on geometry and mechanics formed an important part of the works studied in the Islāmic world.

Translation of Greek texts

Of Euclid's works, the *Elements,* the *Data,* the *Optics,* the *Phaenomena,* and *On Divisions* were translated. Of Archimedes' works only two—*Sphere and Cylinder* and *Measurement of the Circle*—are known to have been translated, but these were sufficient to stimulate independent researches from the 9th to the 15th century. On the other hand, virtually all of Apollonius' works were translated, and of Diophantus and Menelaus one book each, the *Arithmetica* and the *Sphaerica,* respectively, were translated into Arabic. Finally, the translation of Ptolemy's *Almagest* furnished important astronomical material.

Of the minor writings, Diocles' treatise on mirrors, Theodosius' *Spherics,* Pappus' work on mechanics, Ptolemy's *Planisphaerium,* and Hypsicles' treatises on regular polyhedra (the so-called Books XIV and XV of Euclid's *Elements*) were among those translated.

Mathematics in the 9th century. Thābit ibn Qurrah (836–901), a Sabian from Ḥarrān in northern Mesopotamia, was an important translator and reviser of these Greek works. In addition to translating works of the major Greek mathematicians (for the Banū Mūsā, among others), he was a court physician. He also translated Nicomachus of Gerasa's *Arithmetic* and discovered a beautiful rule for finding amicable numbers, a pair of numbers such that each number is the sum of the set of proper divisors of the other number. The investigation of such numbers formed a continuing tradition in Islām. Kamāl ad-Dīn al-Fārisī (d. *c.* 1320) gave the pair 17,926 and 18,416 as an example of Thābit's rule, and in the 17th century Muḥammad Bāqir Yazdī gave the pair 9,363,584 and 9,437,056.

One scientist typical of the 9th century was Muḥammad ibn Mūsā al-Khwārizmī. Working in the House of Wisdom, he introduced Indian material in his astronomical works and also wrote an early book explaining Hindu arithmetic, the *Book of Addition and Subtraction According to the Hindu Calculation*. In another work, the *Book of Restoring and Balancing*, he provided a systematic introduction to algebra, including a theory of quadratic equations. Both works had important consequences for Islāmic mathematics. *Hindu Calculation* began a tradition of arithmetic books that, by the middle of the next century, led to the invention of decimal fractions (complete with a decimal point), and his *Restoring and Balancing* became the point of departure and model for later writers such as the Egyptian Abū Kāmil. Both books were translated into Latin, and *Restoring and Balancing* was the origin of the word algebra, from the Arabic word for "restoring" in its title (*al-jabr*). The *Hindu Calculation*, from a Latin form of the author's name, *algorismi*, yielded the word algorithm.

Al-Khwārizmī's algebra also served as a model for later writers in its application of arithmetic and algebra to the distribution of inheritances according to the complex requirements of Muslim religious law. This tradition of service to the Islāmic faith was an enduring feature of mathematical work in Islām and one which, in the eyes of many, justified the study of secular learning. In the same category are al-Khwārizmī's method of calculating the time of visibility of the new moon (which signals the beginning of the Muslim month) and the expositions by astronomers of methods for finding the direction to Mecca for the five daily prayers.

Mathematics in the 10th century. Islāmic scientists in the 10th century were involved in three major mathematical projects: the completion of arithmetic algorithms, the development of algebra, and the extension of geometry.

The first of these projects led to the appearance of three complete numeration systems, one of which was the finger arithmetic used by the scribes and treasury officials. This ancient arithmetic system, which became known throughout the East and Europe, employed mental arithmetic and a system of storing intermediate results on the fingers as an aid to memory. (Its use of unit fractions recalls the Egyptian system.) During the 10th and 11th centuries capable mathematicians, such as Abū al-Wafā' (940–997/8), wrote on this system, but it was eventually replaced by the decimal system. Arithmetic

A second common system was the base-60 numeration inherited from the Babylonians via the Greeks and known as the arithmetic of the astronomers. Although astronomers used this system for their tables, they usually converted numbers to the decimal system for complicated calculations and then converted the answer back to sexagesimals.

The third system was Indian arithmetic, whose basic numeral forms, complete with the zero, eastern Islām took over from the Hindus. (Different forms of the numerals, whose origins are not entirely clear, were used in the western part of Islām.) The basic algorithms also came from India, but these were adapted by al-Uqlīdisī (*c.* 950) to pen and paper instead of the traditional dust board, a move that helped to popularize this system. Also, the arithmetic algorithms were completed in two ways: by the extension of root-extraction procedures, known to Hindus and Greeks only for square and cube roots, to roots of higher degree, and by the extension of the Hindu decimal system for whole numbers to include decimal fractions. These fractions appear simply as computational devices in the work of both al-Uqlīdisī and al-Baghdādī (*c.* 1000), but in subsequent centuries they received systematic treatment as a general method. As for extraction of roots, Abū al-Wafā' wrote a treatise (now lost) on the topic, and Omar Khayyam ('Umar al-Khayyāmī [1048–1131]) solved the general problem of extracting roots of any desired degree. Omar's treatise, too, is lost, but the method is known from other writers, and it appears that a major step in its development was al-Karajī's 10th-century derivation by means of mathematical induction of the binomial theorem for whole-number exponents—*i.e.*, his discovery that

$$(a+b)^n = a^n + na^{n-1}b + \frac{n(n-1)}{2}\,a^{n-2}b^2 + \frac{n(n-1)(n-2)}{2\cdot 3}\,a^{n-3}b^3 + \ldots + nab^{n-1} + b^n.$$

During the 10th century Islāmic algebraists progressed from al-Khwārizmī's quadratic polynomials to the mastery of the algebra of expressions involving arbitrary positive or negative integral powers of the unknown. Several algebraists explicitly stressed the analogy between the rules for working with powers of the unknown in algebra and those for working with powers of 10 in arithmetic, and there was interaction between the development of arithmetic and algebra from the 10th to the 12th century. A 12th-century student of al-Karajī's works, as-Samaw'al, was able to approximate the quotient $(20x^2 + 30x)/(6x^2 + 12)$ as Algebra

$$3\frac{1}{3} + 5\left(\frac{1}{x}\right) - 6\frac{2}{3}\left(\frac{1}{x^2}\right) - 10\left(\frac{1}{x^3}\right) + \ldots - 40\left(\frac{1}{x^7}\right)$$

and also gave a rule for finding the coefficients of the successive powers of $1/x$. Although none of this employed symbolic algebra, algebraic symbolism was in use by the 14th century in the western part of the Islāmic world. The context for this well-developed symbolism was, it seems, commentaries that were destined for teaching purposes, such as that of Ibn Qunfūdh (1330–1407) of Algeria on the algebra of Ibn al-Bannā' (1256–1321) of Morocco.

Other parts of algebra developed as well. Both Greeks and Hindus had studied indeterminate equations, and the translation of this material and the application of the newly developed algebra led to the investigation of Diophantine equations by writers like Abū Kāmil, al-Karajī, and Abū Ja'far al-Khāzin (first half of 10th century), as well as to attempts to prove a special case of what is now known as Fermat's last theorem, namely that there are no rational solutions to $x^3 + y^3 = z^3$. The great scientist Alhazen (Ibn al-Haytham [965–1041]) solved problems involving congruences by what is now called Wilson's theorem, which states that, if p is a prime, then p divides $(p-1)\times(p-2)\ldots\times 2\times 1 + 1$, and al-Baghdādī gave a variant of the idea of amicable numbers by defining two numbers to "balance" if the sums of their divisors are equal.

However, not only arithmetic and algebra but geometry too underwent extensive development. Thābit ibn Qurrah, his grandson Ibrāhīm ibn Sinān (909–946), Abū Sahl al-Kūhī (d. *c.* 995), and Alhazen solved problems involving the pure geometry of conic sections, including the areas and volumes of plane and solid figures formed from them, and also investigated the optical properties of mirrors made from conic sections. Ibrāhīm ibn Sinān, Abu Sahl al-Kūhī, and Alhazen used the ancient technique of analysis to reduce the solution of problems to constructions involving conic sections. (Alhazen, for example, used this method to find the point on a convex spherical mirror at which a given object is seen by a given observer.) Thābit and Ibrāhīm showed how to design the curves needed for sundials. Abū al-Wafā', whose book on the arithmetic of the scribes is mentioned above, also wrote on geometric methods needed by artisans. Geometry

In addition, in the late 10th century Abū al-Wafā' and the prince Abū Naṣr Manṣur stated and proved theorems

of plane and spherical geometry that could be applied by astronomers and geographers, including the laws of sines and tangents. Abū Naṣr's pupil al-Bīrūnī (973–1050), who produced a vast amount of high-quality work, was one of the masters in applying these theorems to astronomy and to such problems in mathematical geography as the determination of latitudes and longitudes, the distances between cities, and the direction from one city to another.

Omar Khayyam. The mathematician and poet Omar Khayyam was born in Neyshābūr (in modern Iran) only a few years before al-Bīrūnī's death. He later lived in Samarkand and Eṣfahān, and his brilliant work there continued many of the main lines of development in 19th-century mathematics. Not only did he discover a general method of extracting roots of arbitrary high degree, but his *Algebra* contains the first complete treatment of the solution of cubic equations. Omar did this by means of conic sections, but he declared his hope that his successors would succeed where he had failed in finding an algebraic formula for the roots.

Euclid's parallel postulate

Omar was also a part of an Islāmic tradition, which included Thābit and Alhazen, of investigating Euclid's parallel postulate. To this tradition Omar contributed the idea of a quadrilateral with two congruent sides perpendicular to the base. The parallel postulate would be proved, Omar recognized, if he could show that the remaining two angles were right angles. In this he failed, but his question about the quadrilateral became the standard way of discussing the parallel postulate.

That postulate, however, was only one of the questions on the foundations of mathematics that interested Islāmic scientists. Another was the definition of ratios. Omar Khayyam, along with others before him, felt that the theory in Euclid's Book V was logically satisfactory but intuitively unappealing, so he proved that a definition known to Aristotle was equivalent to that given in Euclid. In fact, Omar argued that ratios should be regarded as "ideal numbers," and so he conceived of a much broader system of numbers than that used since Greek antiquity, that of the positive real numbers.

Islāmic mathematics to the 15th century. In the 12th century the physician as-Samaw'al continued and completed the work of al-Karajī in algebra and also provided a systematic treatment of decimal fractions as a means of approximating irrational quantities. In his method of finding roots of pure equations, $x^n = N$, he used what is now known as Horner's method to expand the binomial $(a + y)^n$. His contemporary, Sharaf ad-Dīn aṭ-Ṭūsī, late in the 12th century provided a method of approximating the positive roots of arbitrary equations, based on an approach virtually identical to that discovered by François Viète in 16th-century France. The important step here was less the general idea than the development of the numerical algorithms necessary to effect it.

Sharaf ad-Dīn was the discoverer of a device, called the linear astrolabe, that places him in another important Islāmic mathematical tradition, one that centred on the design of new forms of the ancient astronomical instrument known as the astrolabe. The astrolabe, whose mathematical theory is based on the stereographic projection of the sphere, was invented in late antiquity, but its extensive development in Islām made it the pocket watch of the medievals. In its original form, it required a different plate of horizon coordinates for each latitude, but in the 11th century the Spanish Muslim astronomer az-Zarqallu invented a single plate that worked for all latitudes. Slightly earlier, astronomers in the East had experimented with plane projections of the sphere, and al-Bīrūnī invented such a projection that could be used to produce a map of a hemisphere. The culminating masterpiece was the astrolabe of the Syrian Ibn ash-Shāṭir (1305–75), a mathematical tool that could be used to solve all the standard problems of spherical astronomy in five different ways.

Development of trigonometry

On the other hand, Muslim astronomers had developed other methods for solving these problems using the highly accurate trigonometric tables and the new trigonometric theorems they had developed. Out of these developments came the creation of trigonometry as a mathematical discipline, separate from its astronomical applications, by Naṣīr ad-Dīn aṭ-Ṭūsī at his observatory in Marāgheh in the 13th century. (It was there, too, that Naṣīr ad-Dīn's pupil, Quṭb ad-Dīn ash-Shīrāzī [1236–1311], and his pupil, Kamāl ad-Dīn Fārisī, using Alhazen's great work, the *Optics*, were able to give the first mathematically satisfactory explanation of the rainbow.)

Nasīr ad-Dīn's observatory was supported by a grandson of Genghis Khan, Hülegü, who sacked Baghdad in 1258. Ulugh Beg, the grandson of the Mongol conqueror Timur, founded an observatory at Samarkand in the early years of the 15th century. Ulugh Beg was himself a good astronomer, and his five (sexagesimal) place tables of sines and tangents for every minute of arc were one of the great achievements in numerical mathematics up to his time. He was also the patron of Jamshīd al-Kāshī (d. 1429), whose work *The Reckoners' Key* summarizes most of the arithmetic of his time and includes sections on algebra and practical geometry as well. Among al-Kāshī's works are a masterful computation of the value of 2π, which, when expressed in decimal fractions, is accurate to 16 places, as well as the application of a numerical method, now known as fixed-point iteration, for solving the cubic equation with $\sin 1°$ as a root. His work was indeed of a quality deserving Ulugh Beg's description as "known among the famous of the world."

Al-Kāshī lived almost five centuries after the first translations of Arabic material into Latin, and by his time the Islāmic mathematical tradition had given the West not only its first versions of many of the Greek classics but also a complete set of algorithms for Hindu-Arabic arithmetic, plane and spherical trigonometry, and the powerful tool of algebra. Although mathematical inquiry continued in Islām in the centuries after al-Kāshī's time, the mathematical centre of gravity was shifting to the West. That this was so is due, of course, in no small measure to what the Western mathematicians had learned from their Islāmic predecessors during the preceding centuries. (J.L.B.)

European mathematics during the Middle Ages and Renaissance

Until the 11th century only a small part of the Greek mathematical corpus was known in the West. Because almost no one could read Greek, what little was available came from the poor texts written in Latin in the Roman Empire, together with the very few Latin translations of Greek works. Of these the most important were the treatises by Boethius, who in about AD 500 made Latin redactions of a number of Greek scientific and logical writings. His *Arithmetic*, which was based on Nicomachus, was well known and was the means by which medieval scholars learned of Pythagorean number theory. Boethius and Cassiodorus provided the material for the part of the monastic education called the quadrivium: arithmetic, geometry, astronomy, and music theory. Together with the trivium (grammar, logic, rhetoric), these subjects formed the seven liberal arts, which were taught in the monasteries, cathedral schools, and, from the 12th century on, in the universities and which constituted the principal university instruction until modern times.

Monastic education

For monastic life it sufficed to know how to calculate with Roman numerals. The principal application of arithmetic was a method for determining the date of Easter, the computus, that was based on the lunar cycle of 19 solar years (*i.e.*, 235 lunar revolutions) and the 28-year solar cycle. Between the time of Bede (d. 735), when the system was fully developed, and about 1500, the computus was reduced to a series of verses that were learned by rote. Until the 12th century, geometry was largely concerned with approximate formulas for measuring areas and volumes in the tradition of the Roman surveyors. About AD 1000 the French scholar Gerbert of Aurillac, later Pope Sylvester II, introduced a type of abacus, in which numbers were represented by stones bearing Arabic numerals. Such novelties were known to very few.

The transmission of Greek and Arabic learning. In the 11th century a new phase of mathematics began with the translations from Arabic. Scholars throughout Europe went to Toledo, Córdoba, and elsewhere in Spain to translate

into Latin the accumulated learning of the Muslims. Along with philosophy, astronomy, astrology, and medicine, important mathematical achievements of the Greek, Indian, and Islāmic civilizations became available in the West. Particularly important were Euclid's *Elements*, the works of Archimedes, and al-Khwārizmī's treatises on arithmetic and algebra. Western texts called *algorismus* (a Latin form of the name al-Khwārizmī), introduced the Hindu-Arabic numerals and applied them in calculations. Thus modern numerals first came into use in universities and then became common among merchants and other laymen. It should be noted that, up to the 15th century, calculations were often performed with board and counters. Reckoning with Hindu-Arabic numerals was used by merchants at least from the time of Leonardo of Pisa (beginning of the 13th century) first in Italy, then in the trading cities of southern Germany and France, where *maestri d'abbaco* or *Rechenmeister* taught commercial arithmetic in the various vernaculars. Some schools were private, while others were run by the community.

The universities. Mathematics was studied from a theoretical standpoint in the universities. The universities of Paris and Oxford, which were founded relatively early (*c.* 1200), were centres for mathematics and philosophy. Of particular importance in these universities were the Arabic-based versions of Euclid, of which there were at least four by the 12th century. Of the numerous redactions and compendia which were made, that of Campanus (*c.* 1250; first printed in 1482) was easily the most popular, serving as a textbook for many generations. Such redactions of the *Elements* were made to help students not only to understand Euclid's textbook but also to handle other, particularly philosophical, questions suggested by passages in Aristotle. The ratio theory of the *Elements* provided a means of expressing the various relations of the quantities associated with moving bodies, relations that now would be expressed by formulas. Also in Euclid were to be found methods of analyzing infinity and continuity (paradoxically, because Euclid always avoided infinity).

Influence of Euclid's *Elements*

Studies of such questions led not only to new results but also to a new approach to what is now called physics. Thomas Bradwardine, who was active in Merton College, Oxford, in the first half of the 14th century, was one of the first medieval scholars to ask whether the continuum can be divided infinitely, or whether there are smallest parts (indivisibles). Among other topics, he compared different geometric shapes in terms of the multitude of points that were assumed to compose them, and from such an approach paradoxes were generated that were not to be solved for centuries. Another fertile question stemming from Euclid concerned the angle between a circle and a line tangent to it (called the horn angle): if this angle is not zero, a contradiction quickly ensues, but, if it is zero, then, by definition, there can be no angle. For the relation of force, resistance, and the speed of the body moved by this force, Bradwardine suggested an exponential law. Nicholas Oresme (d. 1382) extended Bradwardine's ideas to fractional exponents.

Another question having to do with the quantification of qualities, the so-called latitude of forms, began to be discussed at about this time in Paris and in Merton College, Oxford. Various Aristotelian qualities (*e.g.*, heat, density, and velocity) were assigned an intensity and extension, which were sometimes represented by the height and bases (respectively) of a geometric figure. The area of the figure was then considered to represent the quantity of the quality. In the important case in which the quality is the motion of a body, the intensity its speed, and the extension its time, the area of the figure was taken to represent the distance covered by the body. Uniformly accelerated motion starting at zero velocity gives rise to a triangular figure (see Figure 11). It was proved by the Merton school that the quantity of motion in such a case is equal to the quantity of a uniform motion at the speed achieved halfway through the accelerated motion; in modern formulation: $s = \frac{1}{2}at^2$ (Merton rule). Discussions like this certainly influenced Galileo indirectly and may have influenced the founding of coordinate geometry in the 17th century. Another important development in the scholastic "calculations" was the summation of infinite series.

The Merton rule

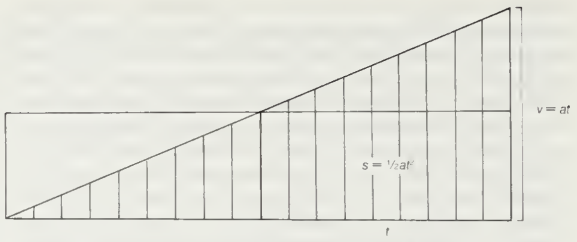

Figure 11: Uniformly accelerated motion; s = speed, a = acceleration, t = time, and v = velocity.

Basing his work on translated Greek sources, the German mathematician and astronomer Regiomontanus wrote the first book in the West on plane and spherical trigonometry independent of astronomy in about 1464 (printed in 1533). He also published tables of sines and tangents that were in constant use for more than two centuries.

The Renaissance. Italian artists and merchants influenced the mathematics of the late Middle Ages and the Renaissance in several ways. In the 15th century a group of Tuscan artists, including Filippo Brunelleschi, Leon Battista Alberti, and Leonardo da Vinci, incorporated linear perspective into their practice and teaching, about a century before the subject was formally treated by mathematicians. Italian *maestri d'abbaco* tried, albeit unsuccessfully, to solve nontrivial cubic equations. In fact, the first general solution was found by Scipione Del Ferro at the beginning of the 16th century and rediscovered by Niccolò Tartaglia several years later. The solution was published by Girolamo Cardano in his *Ars magna* in 1545, together with Lodovico Ferrari's solution of the quartic equation.

By 1380 an algebraic symbolism had been developed in Italy in which letters were used for the unknown, for its square, and for constants. The symbols used today for the unknown (for example, x), the square root sign, and the signs + and − came into general use in southern Germany beginning in about 1450. They were used by Regiomontanus and by Fridericus Gerhart and received an impetus in about 1486 at the University of Leipzig from Johann Widman. The idea of distinguishing between known and unknown quantities in algebra was first consistently applied by François Viète, with vowels for unknown and consonants for known quantities. Viète found some relations between the coefficients of an equation and its roots. This was suggestive of the idea, explicitly stated by Albert Girard in 1629 and proved by Gauss in 1799, that an equation of degree n has n roots. Complex numbers, which are implicit in such ideas, were gradually accepted about the time of Rafael Bombelli (d. 1572), who used them in connection with the cubic.

Apollonius' *Conics* and the investigations of areas (quadratures) and of volumes (cubatures) of Archimedes formed part of the humanistic learning of the 16th century. These studies strongly influenced the later developments of analytic geometry, the infinitesimal calculus, and the theory of functions, subjects that were developed in the 17th century. (Me.F.)

Mathematics in the 17th and 18th centuries

THE 17TH CENTURY

The 17th century, the period of the scientific revolution, witnessed the consolidation of Copernican heliocentric astronomy and the establishment of inertial physics in the work of Kepler, Galileo, Descartes, and Newton. This period was also one of intense activity and innovation in mathematics. Advances in numerical calculation, the development of symbolic algebra and analytic geometry, and the invention of the differential and integral calculus resulted in a major expansion of the subject areas of mathematics. By the end of the 17th century a program of research based in analysis had replaced classical Greek geometry at the centre of advanced mathematics. In the next century this program would continue to develop in close association with physics, more particularly mechanics and theoretical astronomy. The extensive use of

Development of analysis

analytic methods, the incorporation of applied subjects, and the adoption of a pragmatic attitude to questions of logical rigour distinguished the new mathematics from traditional geometry.

Institutional background. Until the middle of the 17th century, mathematicians worked alone or in small groups, publishing their work in books or communicating with other researchers by letter. At a time when people were often slow to publish, "invisible colleges," networks of scientists who corresponded privately, played an important role in coordinating and stimulating mathematical research. Marin Mersenne in Paris acted as a clearinghouse for new results, informing his many correspondents—including Fermat, Descartes, Blaise Pascal, Gilles Personne de Roberval, and Galileo—of challenge problems and novel solutions. Later in the century John Collins, librarian of London's Royal Society, performed a similar function among British mathematicians.

In 1660 the Royal Society of London was founded, to be followed in 1666 by the Academy of Sciences in France, in 1700 by the Berlin Academy, and in 1724 by the St. Petersburg Academy. The official publications sponsored by the academies, as well as independent journals such as the *Acta Eruditorum* (founded in 1682), made possible the open and prompt communication of research findings. Although universities in the 17th century provided some support for mathematics, they became increasingly ineffective as state-supported academies assumed direction of advanced research.

Numerical calculation. The development of new methods of numerical calculation was a response to the increased practical demands of numerical computation, particularly in trigonometry, navigation, and astronomy. New ideas spread quickly across Europe and resulted by 1630 in a major revolution in numerical practice.

Simon Stevin of Holland, in his short pamphlet *La Disme* (1585), introduced decimal fractions to Europe and showed how to extend the principles of Hindu-Arabic arithmetic to calculation with these numbers. Stevin emphasized the utility of decimal arithmetic "for all accounts that are encountered in the affairs of men," and he explained in an appendix how it could be applied to surveying, stereometry, astronomy, and mensuration. His idea was to extend the base-10 positional principle to numbers with fractional parts, with a corresponding extension of notation to cover these cases. In his system the number 237.578 was denoted

$$237\ ⓪\ 5\ ①\ 7\ ②\ 8\ ③,$$

in which the digits to the left of the zero are the integral part of the number. To the right of the zero are the digits of the fractional part, with each digit succeeded by a circled number that indicates the negative power to which 10 is raised. Stevin showed how the usual arithmetic of whole numbers could be extended to decimal fractions using rules that determined the positioning of the negative powers of 10.

In addition to its practical utility, *La Disme* was significant for the way it undermined the dominant style of classical Greek geometry in theoretical mathematics. Stevin's proposal required a rejection of the distinction in Euclidean geometry between magnitude, which is continuous, and number, which is a multitude of indivisible units. For Euclid, unity, or one, was a special sort of thing, not number but the origin, or principle, of number. The introduction of decimal fractions seemed to imply that the unit could be subdivided and that arbitrary continuous magnitude could be represented numerically; it implicitly supposed the concept of a general positive real number.

Logarithms

Tables of logarithms were first published in 1614 by the Scottish baron John Napier in his treatise *Mirifici Logarithmorum Canonis Descriptio* (*Description of the Marvelous Canon of Logarithms*). This work was followed (posthumously) five years later by another in which Napier set forth the principles used in the construction of his tables. The basic idea behind logarithms is that addition and subtraction are easier to perform than multiplication and division, which, as Napier observed, require a "tedious expenditure of time" and are subject to "slippery errors." By the law of exponents, $a^n a^m = a^{n+m}$, that is, in the multiplication of numbers the exponents are related additively. By correlating the geometric sequence of numbers $a, a^2, a^3, \ldots$ (a is called the base) and the arithmetic sequence $1, 2, 3, \ldots$ and interpolating to fractional values, it is possible to reduce the problem of multiplication and division to one of addition and subtraction. To do this Napier chose a base that was very close to 1, differing from it by only $1/10^7$. The resulting geometric sequence therefore yielded a dense set of values, suitable for constructing a table.

In his work of 1619 Napier presented an interesting kinematic model to generate the geometric and arithmetic sequences used in the construction of his tables. Assume two particles move along separate lines from given initial points. The particles begin moving at the same instant with the same velocity. The first particle continues to move with a speed that is decreasing, proportional at each instant to the distance remaining between it and some given fixed point on the line. The second particle moves with a constant speed equal to its initial velocity. Given any increment of time, the distances traveled by the first particle in successive increments form a geometrically decreasing sequence. The corresponding distances traveled by the second particle form an arithmetically increasing sequence. Napier was able to use this model to derive theorems yielding precise limits to approximate values in the two sequences.

Napier's kinematic model indicated how skilled mathematicians had become by the early 17th century in analyzing nonuniform motion. Kinematic ideas, which appeared frequently in mathematics of the period, provided a clear and visualizable means for the generation of geometric magnitude. The conception of a curve traced by a particle moving through space later played a significant role in the development of the calculus.

Napier's ideas were taken up and revised by the English mathematician Henry Briggs, the first Savilian professor of geometry at Oxford. In 1624 Briggs published an extensive table of common logarithms, or logarithms to the base 10. Because the base was no longer close to 1, the table could not be obtained as simply as Napier's, and Briggs therefore devised techniques involving the calculus of finite differences to facilitate calculation of the entries. He also devised interpolation procedures of great computational efficiency to obtain intermediate values.

In Switzerland the instrument maker Joost Bürgi arrived at the idea for logarithms independently of Napier, although he did not publish his results until 1620. Four years later a table of logarithms prepared by Johannes Kepler appeared in Marburg. Both Bürgi and Kepler were astronomical observers, and Kepler included logarithmic tables in his famous Rudolphine Tables, astronomical tabulations of planetary motion derived using the assumption of elliptical orbits about the Sun.

Analytic geometry. The invention of analytic geometry was, next to the differential and integral calculus, the most important mathematical development of the 17th century. Originating in the work of the French mathematicians Viète, Fermat, and Descartes, it had by the middle of the century established itself as a major program of mathematical research.

Two tendencies in contemporary mathematics stimulated the rise of analytic geometry. The first was an increased interest in curves, resulting in part from the recovery and Latin translation of the classical treatises of Apollonius, Archimedes, and Pappus, and in part from the increasing importance of curves in such applied fields as astronomy, mechanics, optics, and stereometry. The second was the emergence a century earlier of an established algebraic practice in the work of the Italian and German algebraists and its subsequent shaping into a powerful mathematical tool by Viète at the end of the century.

Influence of Greek geometers

Viète was a prominent representative of the humanist movement in mathematics that set itself the project of restoring and furthering the achievements of the classical Greek geometers. In his *In artem analyticem isagoge* ("Introduction to the Analytic Arts"; 1591) Viète, as part

of his program of rediscovering the method of analysis used by the ancient Greek mathematicians, proposed new algebraic methods that employed variables, constants, and equations, but he saw this as an advancement over the ancient method, a view he arrived at by comparing the geometric analysis contained in Book VII of Pappus' *Collection* with the arithmetic analysis of Diophantus' *Arithmetica*. Pappus had employed an analytic method for the discovery of theorems and the construction of problems; in analysis, by contrast to synthesis, one proceeds from what is sought until one arrives at something known. In approaching an arithmetic problem by laying down an equation among known and unknown magnitudes and then solving for the unknown, one was, Viète reasoned, following an "analytic" procedure.

Viète's notation

Viète introduced the concept of algebraic variable, which he denoted using a capital vowel (*A, E, I, O, U*) as well as the concept of parameter (an unspecified constant quantity), denoted by a capital consonant (*B, C, D,* and so on). In his system the equation $5BA^2 - 2CA + A^3 = D$ would appear as *B*5 in *A* quad − *C* plano 2 in *A* + *A* cub aequatur *D* solido.

Viète retained the classical principle of homogeneity, according to which terms added together must all be of the same dimension. In the above equation, for example, each of the terms has the dimension of a solid or cube; thus the constant *C*, which denotes a plane, is combined with *A* to form a quantity having the dimension of a solid.

It should be noted that in Viète's scheme the symbol *A* is part of the expression for the object obtained by operating on the magnitude denoted by *A*. Thus operations on the quantities denoted by the variables are reflected in the algebraic notation itself. This innovation, considered by historians of mathematics to be a major conceptual advance in algebra, facilitated the study of the symbolic solution of algebraic equations and led to the creation of the first conscious theory of equations.

After Viète's death the analytic art was applied to the study of curves by his countrymen Fermat and Descartes. Both men were motivated by the same goal, to apply the new algebraic techniques to Apollonius' theory of loci as preserved in Pappus' *Collection*. The most celebrated of these problems consisted of finding the curve or locus traced by a point whose distances from several fixed lines satisfied a given relation.

Fermat adopted Viète's notation in his paper of 1636, "Ad Locos Planos et Solidos Isagoge" ("Introduction to Plane and Solid Loci"). The title of the paper refers to the ancient classification of curves as plane (straight lines, circles), solid (ellipses, parabolas, and hyperbolas), or linear (curves defined kinematically or by a locus condition). Fermat considered an equation among two variables. One of the variables represented a line measured horizontally from a given initial point, while the other represented a second line positioned at the end of the first line and inclined at a fixed angle to the horizontal. As the first variable varied in magnitude, the second took on a value determined by the equation, and the endpoint of the second line traced out a curve in space. By means of this construction Fermat was able to formulate the fundamental principle of analytic geometry:

> Whenever two unknown quantities are found in final equality, there results a locus fixed in place, and the endpoint of one of these unknown quantities describes a straight line or a curve.

The principle implied a correspondence between two different classes of mathematical objects, geometric curves and algebraic equations. In the paper of 1636 Fermat showed that, if the equation is a quadratic, then the curve is a conic section, that is, an ellipse, parabola, or hyperbola. He also showed that the determination of the curve given by an equation is simplified by a transformation involving a change of variables to an equation in standard form.

La Géométrie

Descartes's *La Géométrie* appeared in 1637 as an appendix to his famous *Discours de la méthode*, the treatise that presented the foundation of his philosophical system. Although supposedly an example from mathematics of his rational method, *La Géométrie* was a technical treatise understandable independently of philosophy. It was destined to become one of the most influential books in the history of mathematics.

In the opening sections of *La Géométrie* Descartes introduced two innovations. In place of Viète's notation he initiated the modern practice of denoting variables by letters at the end of the alphabet (*x, y, z*) and parameters by letters at the beginning of the alphabet (*a, b, c*) and of using exponential notation to indicate powers of *x* (x^2, x^3, . . .). More significantly conceptually, he set aside Viète's principle of homogeneity, showing by means of a simple construction how to represent multiplication and division of lines by lines; thus all magnitudes (lines, areas, and volumes) could be represented independently of their dimension in the same way.

Descartes's goal in *La Géométrie* was to achieve the construction of solutions to geometric problems by means of instruments that were acceptable generalizations of ruler and compass. Algebra was a tool to be used in this program:

> If, then, we wish to solve any problem, we first suppose the solution already effected, and give names to all the lines that seem necessary for its construction—to those that are unknown as well as to those that are known. Then, making no distinction in any way between known and unknown lines, we must unravel the difficulty in any way that shows most naturally the relations between these lines, until we find it possible to express a single quantity in two ways. This will constitute an equation, since the terms of one of these two expressions are together equal to the terms of the other.

In the problem of Apollonius, for example, one sought to find the locus of points whose distances from a collection of fixed lines satisfied a given relation. One used this relation to derive an equation and then obtained points on the curve given by the roots of the equation using a geometric procedure involving acceptable instruments of construction.

Descartes described instruments more general than the compass for drawing "geometric" curves. He stipulated that the parts of the instrument be linked together so that the ratio of the motions of the parts could be knowable. This restriction excluded "mechanical" curves generated by kinematic processes. The Archimedean spiral, for example, was generated by a point moving on a line as the line rotated uniformly about the origin. The ratio of the circumference to the diameter did not permit exact determination:

> the ratios between straight and curved lines are not known, and I even believe cannot be discovered by men, and therefore no conclusion based upon such ratios can be accepted as rigorous and exact.

Geometric curves

Descartes concluded that a geometric or nonmechanical curve was one whose equation $f(x, y) = 0$ was a polynomial of finite degree in two variables. He wished to restrict mathematics to the consideration of such curves.

Descartes's emphasis on construction reflected his classical orientation. His conservatism with respect to what curves were acceptable in mathematics further distinguished him as a traditional thinker. At the time of his death in 1650, he had been overtaken by events, as research moved away from questions of construction to problems of finding areas (then called problems of quadrature) and tangents. The geometric objects that were then of growing interest were precisely the mechanical curves that Descartes had wished to banish from mathematics.

Following the important results achieved in the 16th century by Cardano and the Italian algebraists, the theory of algebraic equations reached an impasse. The ideas needed to investigate equations of degree higher than four were slow to develop. The immediate historical influence of Viète, Fermat, and Descartes was to furnish algebraic methods for the investigation of curves. A vigorous school of research became established in Leiden around Frans van Schooten, a Dutch mathematician who edited and published in 1649 a Latin translation of *La Géométrie*. Van Schooten published a second two-volume translation of the same work in 1659–1661 that also contained mathematical appendices by three of his disciples, Johan de Witt, Johan Hudde, and Hendrick van Heuraet. The Leiden group of mathematicians, which also included

Christiaan Huygens, was in large part responsible for the rapid development of Cartesian geometry in the middle of the century.

The calculus. The historian Carl Boyer has called the calculus "the most effective instrument for scientific investigation that mathematics has ever produced." As the mathematics of variability and change, the calculus was the characteristic product of the scientific revolution. The subject was properly the invention of two mathematicians, the German Gottfried Wilhelm Leibniz and the Englishman Isaac Newton. Both men published their researches in the 1680s, Leibniz in 1684 in the recently founded journal *Acta Eruditorum* and Newton in 1687 in his great treatise *Principia Mathematica.* Although a bitter dispute over priority developed later among followers of the two men, it is now clear that they each arrived at the calculus independently.

The calculus developed from techniques to solve two types of problems, the determination of areas and volumes and the calculation of tangents to curves. In classical geometry Archimedes had advanced furthest in this part of mathematics, having used the method of exhaustion to establish rigorously various results on areas and volumes and having derived for some curves (*e.g.,* the spiral) significant results concerning tangents. In the early 17th century there was a sharp revival of interest in both classes of problems. The decades between 1610 and 1670, referred to in the history of mathematics as "the precalculus period," were at a time of remarkable activity in which researchers throughout Europe contributed novel solutions and competed with each other to arrive at important new methods.

The precalculus period. In his treatise *Geometria Indivisibilibus Continuorum* (1635) (*Geometry by Indivisibles of Continuum*) Cavalieri, a professor of mathematics at the University of Bologna, formulated a systematic method for the determination of areas and volumes. As had Archimedes, Cavalieri regarded a plane figure as being composed of a collection of indivisible lines, "all the lines" of the plane figure. The collection was generated by a fixed line moving through space parallel to itself. Cavalieri showed that these collections could be interpreted as magnitudes obeying the rules of Euclidean ratio theory. In proposition 4 of Book II, he derived the result that is written today as

Cavalieri

$$\int_0^1 x^2 dx = \frac{1}{3};$$

> Let there be given a parallelogram in which a diagonal is drawn; then "all the squares" of the parallelogram will be triple "all the squares" of each of the triangles determined by the diagonal.

Cavalieri showed that this proposition could be interpreted in different ways, as asserting that the volume of a cone is one-third the volume of the circumscribed cylinder or that the area under a segment of a parabola is one-third the area of the associated rectangle. In a later treatise he generalized the result by proving

$$\int_0^1 x^n dx = \frac{1}{(n+1)}$$

for $n = 3$ to $n = 9$. To establish these results he introduced transformations among the variables of the problem, using a result equivalent to the binomial theorem for integral exponents. The ideas involved went beyond anything that had appeared in the classical Archimedean theory of content.

Although Cavalieri was successful in formulating a systematic method based on general concepts, his ideas were not easy to apply. The derivation of very simple results required intricate geometric considerations, and the turgid style of the *Geometria Indivisibilibus* was a barrier to its reception.

John Wallis presented a quite different approach to the theory of quadratures in his *Arithmetica Infinitorum* (1655) (*Arithmetic of Infinities).* Wallis, a successor to Henry Briggs as the Savilian professor of geometry at Oxford, was a champion of the new methods of arithmetic algebra that he had learned from his teacher William Oughtred. Wallis expressed the area under a curve as the sum of an infinite series and used clever and unrigorous inductions to determine its value. To calculate the area under the parabola,

$$\int_0^1 x^2 dx,$$

he considered the successive sums

$$\frac{0+1}{1+1} = \frac{1}{3} + \frac{1}{6}, \quad \frac{0+1+4}{4+4+4} = \frac{1}{3} + \frac{1}{12}, \quad \frac{0+1+4+9}{9+9+9+9} = \frac{1}{3} + \frac{1}{18}$$

and inferred by "induction" the general relation

$$\frac{0^2 + 1^2 + 2^2 \ldots + n^2}{n^2 + n^2 + n^2 \ldots + n^2} = \frac{1}{3} + \frac{1}{6n}.$$

By letting the number of terms be infinite, he obtained $1/3$ as the limiting value of the expression. With more complicated curves he achieved very impressive results, including the infinite expression now known as Wallis' product:

$$\frac{4}{\pi} = \frac{3}{2} \cdot \frac{3}{4} \cdot \frac{5}{4} \cdot \frac{5}{6} \cdot \frac{7}{6} \cdot \ldots.$$

Research on the determination of tangents, the other subject leading to the calculus, proceeded along different lines. In *La Géométrie* Descartes had presented a method that could in principle be applied to any algebraic or "geometric" curve—*i.e.,* any curve whose equation was a polynomial of finite degree in two variables. The method depended upon finding the normal, the line perpendicular to the tangent, using the algebraic condition that it be the unique radius to intersect the curve in only one point. Descartes's method was simplified by Hudde, a member of the Leiden group of mathematicians, and was published in 1659 in van Schooten's edition of *La Géométrie.*

A class of curves of growing interest in the 17th century were those generated kinematically by a point moving through space. The famous cycloidal curve, for example, was traced by a point on the perimeter of a wheel that rolled on a line without slipping or sliding. These curves were nonalgebraic and hence could not be treated by Descartes's method. Gilles de Roberval, professor at the Collège Royale in Paris, devised a method borrowed from dynamics to determine their tangents. In his analysis of projectile motion Galileo had shown that the instantaneous velocity of a particle is compounded of two separate motions: a constant horizontal motion and an increasing vertical motion due to gravity. If the motion of the generating point of a kinematic curve is likewise regarded as the sum of two velocities, then the tangent will lie in the direction of their sum. Roberval applied this idea to several different kinematic curves, obtaining results that were often ingenious and elegant.

Non-algebraic curves

In an essay of 1636 circulated among French mathematicians, Fermat presented a method of tangents adapted from a procedure he had devised to determine maxima and minima and used it to find tangents to several algebraic curves of the form $y = x^n$. His account was short and contained no explanation of the mathematical basis of the new method. It is possible to see in his procedure an argument involving infinitesimals, and Fermat has sometimes been proclaimed as the discoverer of the differential calculus. Modern historical study, however, suggests that he was working with concepts introduced by Viète and that his method was based on finite algebraic ideas.

Isaac Barrow, the Lucasian professor of mathematics at Cambridge, published in 1670 his *Lectiones Geometricae* (*Geometrical Lectures*), a treatise that more than any other anticipated the unifying ideas of the calculus. In it he adopted a purely geometric form of exposition to show how the determinations of areas and tangents are inverse problems. He began with a curve and considered the slope of its tangent corresponding to each value of the abscissa. He then defined an auxiliary curve by the condition that its ordinate be equal to this slope and showed that the area under the auxiliary curve corresponding to a given

abscissa is equal to the rectangle whose sides are unity and the ordinate of the original curve. When reformulated analytically, this result expresses the inverse character of differentiation and integration, the fundamental theorem of the calculus. Although Barrow's decision to proceed geometrically prevented him from taking the final step to a true calculus, his lectures influenced both Newton and Leibniz.

Newton and Leibniz. The essential insight of Newton and Leibniz was to use Cartesian algebra to synthesize the earlier results and to develop algorithms that could be applied uniformly to a wide class of problems. The formative period of Newton's researches was from 1665 to 1670, while Leibniz worked a few years later, in the 1670s. Their contributions differ in origin, development, and influence, and it is necessary to consider each man separately.

The son of an English farmer, Newton became in 1669 the Lucasian professor of mathematics at Cambridge University. Newton's earliest researches in mathematics grew in 1665 from his study of van Schooten's edition of *La Géométrie* and Wallis' *Arithmetica Infinitorum.* Using the Cartesian equation of the curve, he reformulated Wallis' results, introducing for this purpose infinite sums in the powers of an unknown x, now known as infinite series. Possibly under the influence of Barrow, he used infinitesimals to establish for various curves the inverse relationship of tangents and areas. The operations of differentiation and integration emerged in his work as analytic processes that could be applied generally to investigate curves.

Fluents and fluxions

Unusually sensitive to questions of rigour, Newton at a fairly early stage tried to establish his new method on a sound foundation using ideas from kinematics. A variable was regarded as a "fluent," a magnitude that flows with time; its derivative or rate of change with respect to time was called a "fluxion," denoted by the given variable with a dot above it. The basic problem of the calculus was to investigate relations among fluents and their fluxions. Newton finished a treatise on the method of fluxions as early as 1671, although it was not published until 1736. In the 18th century this method became the preferred approach to the calculus among British mathematicians, especially after the appearance in 1742 of Colin Maclaurin's influential *Treatise of Fluxions.*

Newton first published the calculus in Book I of his great *Philosophiae Naturalis Principia Mathematica* (1687) (*Mathematical Principles of Natural Philosophy*). Originating as a treatise on the dynamics of particles, the *Principia* presented an inertial physics that combined Galileo's mechanics and Kepler's planetary astronomy. It was written in the early 1680s at a time when Newton was reacting against Descartes's science and mathematics. Setting aside the analytic method of fluxions, Newton introduced in 11 introductory lemmas his calculus of first and last ratios, a geometric theory of limits that provided the mathematical basis of his dynamics.

Newton's use of the calculus in the *Principia* is illustrated by proposition 11 of Book I: If the orbit of a particle moving under a centripetal force is an ellipse with the centre of force at one focus, then the force is inversely proportional to the square of the distance from the centre. Because the planets were known by Kepler's laws to move in ellipses with the Sun at one focus, this result supported his inverse square law of gravitation. To establish the proposition, Newton derived an approximate measure for the force by using small lines defined in terms of the radius (the line from the force centre to the particle) and the tangent to the curve at a point. This result expressed geometrically the proportionality of force to vector acceleration. Using properties of the ellipse known from classical geometry, Newton calculated the limit of this measure and showed that it was equal to a constant times one over the square of the radius.

Newton avoided analytical processes in the *Principia* by expressing magnitudes and ratios directly in terms of geometric quantities, both finite and infinitesimal. His decision to eschew analysis constituted a striking rejection of the algebraic methods that had been important in his own early researches on the calculus. Although the *Principia* was of inestimable value for later mechanics, it would be reworked by researchers on the Continent and expressed in the mathematical idiom of the Leibnizian calculus.

Leibniz's interest in mathematics was aroused in 1672 during a visit to Paris, where the Dutch mathematician Christiaan Huygens introduced him to his work on the theory of curves. Under Huygens' tutelage Leibniz immersed himself for the next several years in the study of mathematics. He investigated relationships among the summing and differencing of finite and infinite sequences of numbers. Having read Barrow's geometric lectures, he devised a transformation rule to calculate quadratures, obtaining the famous infinite series for $\pi/4$:

$$\frac{\pi}{4} = \frac{1}{1} - \frac{1}{3} + \frac{1}{5} - \frac{1}{7} + \dots .$$

Notation

Leibniz was interested in questions of logic and notation, of how to construct a *characteristica universalis* for rational investigation. After considerable experimentation he arrived by the late 1670s at an algorithm based on the symbols d and $\int$. He first published his research on differential calculus in 1684 in an article in the *Acta Eruditorum,* "Nova Methodus pro Maximis et Minimis, Itemque Tangentibus, qua nec Fractas nec Irrationales Quantitates Moratur, et Singulare pro illi Calculi Genus" ("A New Method for Maxima and Minima as Well as Tangents, Which Is Impeded Neither by Fractional nor by Irrational Quantities, and a Remarkable Type of Calculus for This"). In this article he introduced the differential dx satisfying the rules $d(x+y) = dx + dy$ and $d(xy) = xdy + ydx$ and illustrated his calculus with a few examples. Two years later he published a second article, "On a Deeply Hidden Geometry," in which he introduced and explained the symbol $\int$ for integration. He stressed the power of his calculus to investigate transcendental curves, the very class of "mechanical" objects Descartes had believed lay beyond the power of analysis, and derived a simple analytical formula for the cycloid.

Leibniz continued to publish results on the new calculus in the *Acta Eruditorum* and began to explore his ideas in extensive correspondence with other scholars. Within a few years he had attracted a group of researchers to promulgate his methods, including the brothers Johann and Jakob Bernoulli in Basel and the priest Pierre Varignon and Guillaume-François-Antoine de L'Hospital in Paris. In 1700 he convinced Frederick III of Prussia to establish the Brandenburg Society of Sciences (later renamed the Berlin Academy of Sciences), with himself appointed president for life.

Leibniz's vigorous espousal of the new calculus, the didactic spirit of his writings, and his ability to attract a community of researchers contributed to his enormous influence on subsequent mathematics. In contrast, Newton's slowness to publish and his personal reticence resulted in a reduced presence within European mathematics. Although the British school in the 18th century included capable researchers, Abraham De Moivre, James Stirling, Brook Taylor, and Maclaurin among them, they failed to establish a program of research comparable to that established by Leibniz's followers on the Continent. There is a certain tragedy in Newton's isolation and his reluctance to acknowledge the superiority of continental analysis. As the historian Michael Mahoney observed:

> Whatever the revolutionary influence of the *Principia,* mathematics would have looked much the same if Newton had never existed. In that endeavour he belonged to a community, and he was far from indispensable to it.

THE 18TH CENTURY

Institutional background. After 1700 a movement to found learned societies on the model of Paris and London spread throughout Europe and the American colonies. The academy was the predominant institution of science until it was displaced by the university in the 19th century. The leading mathematicians of the period, such as Leonhard Euler, Jean Le Rond d'Alembert, and Joseph-Louis Lagrange, pursued academic careers at St. Petersburg, Paris, and London.

The Paris Academy of Sciences

The Paris Academy of Sciences provides an informative study of the 18th-century learned society. The academy was divided into six sections, three for the mathematical and three for the physical sciences. The mathematical sections were for geometry, astronomy, and mechanics, the physical sections for chemistry, anatomy, and botany. Membership in the academy was divided by section, with each section contributing three pensionnaires, two associates, and two adjuncts. There was also a group of free associates, distinguished men of science from the provinces, and foreign associates, eminent international figures in the field. A larger group of 70 corresponding members had partial privileges, including the right to communicate reports to the academy. The administrative core consisted of a permanent secretary, treasurer, president, and vice president. In a given year the average total membership in the academy was 153.

Prominent characteristics of the academy included its small and elite membership, made up heavily of men from the middle class, and its emphasis on the mathematical sciences. In addition to holding regular meetings and publishing memoirs, the academy organized scientific expeditions and administered prize competitions on important mathematical and scientific questions.

The historian Roger Hahn has noted that the academy in the 18th century allowed "the coupling of relative doctrinal freedom on scientific questions with rigorous evaluations by peers," an important characteristic of modern professional science. Academic mathematics and science did, however, foster a stronger individualistic ethos than is usual today. A determined individual such as Euler or Lagrange could emphasize a given program of research through his own work, the publications of the academy, and the setting of the prize competitions. The academy as an institution may have been more conducive to the solitary patterns of research in a theoretical subject like mathematics than it was to the experimental sciences. The separation of research from teaching is perhaps the most striking characteristic that distinguished the academy from the model of university-based science which developed in the 19th century.

Analysis and mechanics. The scientific revolution had bequeathed to mathematics a major program of research in analysis and mechanics. The period from 1700 to 1800, "the century of analysis," witnessed the consolidation of the calculus and its extensive application to mechanics. With expansion came specialization, as different parts of the subject acquired their own identity: ordinary and partial differential equations, calculus of variations, infinite series, and differential geometry. The applications of analysis were also varied, including the theory of the vibrating string, particle dynamics, the theory of rigid bodies, the mechanics of flexible and elastic media, and the theory of compressible and incompressible fluids. Analysis and mechanics developed in close association, with problems in one giving rise to concepts and techniques in the other, and all the leading mathematicians of the period made important contributions to mechanics.

Applications of analysis

The close relationship between mathematics and mechanics in the 18th century had roots extending deep into Enlightenment thought. In the organizational chart of knowledge at the beginning of the preliminary discourse to the *Encyclopédie,* d'Alembert distinguished between "pure" mathematics (geometry, arithmetic, algebra, calculus) and "mixed" mathematics (mechanics, geometric astronomy, optics, art of conjecturing). Mathematics generally was classified as a "science of nature" and separated from logic, a "science of man." The modern disciplinary division between physics and mathematics and the association of the latter with logic had not yet developed.

Mathematical mechanics itself as it was practiced in the 18th century differed in important respects from later physics. The goal of modern physics is to explore the ultimate particulate structure of matter and to arrive at fundamental laws of nature to explain physical phenomena. The character of applied investigation in the 18th century was rather different. The material parts of a given system and their interrelationship were idealized for the purposes of analysis. A material object could be treated as a point-mass (a mathematical point at which it is assumed all the mass of the object is concentrated), as a rigid body, as a continuously deformable medium, and so on. The intent was to obtain a mathematical description of the macroscopic behaviour of the system rather than to ascertain the ultimate physical basis of the phenomena. In this respect the 18th-century viewpoint is closer to modern mathematical engineering than it is to physics.

Mathematical research in the 18th century was coordinated by the Paris, Berlin, and St. Petersburg academies, as well as by several smaller provincial scientific academies and societies. Although England and Scotland were important centres early in the century, with Maclaurin's death in 1746 the British flame was all but extinguished.

History of analysis. The history of analysis in the 18th century can be followed in the official memoirs of the academies and in independently published expository treatises. In the first decades of the century the calculus was cultivated in an atmosphere of intellectual excitement, as mathematicians applied the new methods to a range of problems in the geometry of curves. The brothers Johann and Jakob Bernoulli showed that the shape of a smooth wire along which a particle descends in the least time is the cycloid, a transcendental curve much studied in the previous century. Working in a spirit of keen rivalry, the two brothers arrived at ideas that would later develop into the calculus of variations. In his study of the rectification of the lemniscate, a ribbon-shaped curve discovered by Jakob Bernoulli in 1694, Giulio Carlo Fagnano (1682–1766) introduced ingenious analytic transformations that laid the foundation for the theory of elliptic integrals. Nikolaus I Bernoulli (1687–1759), the nephew of Johann and Jakob, proved the equality of mixed second-order partial derivatives and made important contributions to differential equations by the construction of orthogonal trajectories to families of curves. Pierre Varignon (1654–1722), Johann Bernoulli, and Jakob Hermann (1678–1733) continued to develop analytic dynamics as they adapted Leibniz's calculus to the inertial mechanics of Newton's *Principia.*

Geometric conceptions and problems predominated in the early calculus. This emphasis on the curve as the object of study provided coherence to what was otherwise a disparate collection of analytic techniques. With its continued development, the calculus gradually became removed from its origins in the geometry of curves, and a movement emerged to establish the subject on a purely analytic basis. In a series of textbooks published in the middle of the century, the Swiss mathematician Leonhard Euler systematically accomplished the separation of the calculus from geometry. In his *Introductio in Analysin Infinitorum* (1748; *Introduction to the Analysis of Infinities*) he made the notion of function the central organizing concept of analysis:

Foundations of the calculus

> A function of a variable quantity is an analytical expression composed in any way from the variable and from numbers or constant quantities.

Euler's analytic approach is illustrated by his introduction of the sine and cosine functions. Trigonometric tables had existed since antiquity, and the relations between sines and cosines were commonly used in mathematical astronomy. In the early calculus mathematicians had derived in their study of periodic mechanical phenomena the differential equation

$$\frac{dy}{dx} = \frac{1}{\sqrt{1 - x^2}}$$

and they were able to interpret its solution geometrically in terms of lines and angles in the circle. Euler was the first to introduce the sine and cosine functions as quantities whose relation to other quantities could be studied independently of any geometric diagram.

Euler's analytic approach to the calculus received support from his younger contemporary Joseph-Louis Lagrange, who, following Euler's death in 1783, replaced him as the leader of European mathematics. In 1755 the 19-year-old Lagrange wrote to Euler to announce the discovery of a new algorithm in the calculus of variations, a subject to

which Euler had devoted an important treatise 11 years earlier. Euler had used geometric ideas extensively and had emphasized the need for analytic methods. Lagrange's idea was to introduce the new symbol δ into the calculus and to experiment formally until he had devised an algorithm to obtain the variational equations. Mathematically quite distinct from Euler's procedure, his method required no reference to the geometric configuration. Euler immediately adopted Lagrange's idea, and in the next several years the two men systematically revised the subject using the new techniques.

In 1766 Lagrange was invited by the Prussian king, Frederick II the Great, to become mathematics director of the Berlin Academy. During the next two decades he wrote important memoirs on nearly all of the major areas of mathematics. In 1788 he published his famous *Mécanique analytique*, a treatise that used variational ideas to present mechanics from a unified analytic viewpoint. In the preface Lagrange wrote:

> One will find no Figures in this Work. The methods that I present require neither constructions nor geometrical or mechanical reasonings, but only algebraic operations, subject to a regular and uniform course. Those who admire Analysis, will with pleasure see Mechanics become a new branch of it, and will be grateful to me for having extended its domain.

Following the death of Frederick the Great, Lagrange traveled to Paris to become a pensionnaire of the Academy of Sciences. With the establishment of the École Polytechnique (French: "Polytechnic School") in 1794 he was asked to deliver the lectures on mathematics. There was a concern in European mathematics at the time to place the calculus on a sound basis, and Lagrange used the occasion to develop his ideas for an algebraic foundation of the subject. The lectures were published in 1797 under the title *Théorie des fonctions analytiques* ("Theory of Analytical Functions"), a treatise whose contents were summarized in its longer title "Containing the Principles of the Differential Calculus Disengaged from All Consideration of Infinitesimals, Vanishing Limits or Fluxions and Reduced to the Algebraic Analysis of Finite Quantities." Lagrange published a second treatise on the subject in 1801, a work that appeared in a revised and expanded form in 1806.

The theory of functions of a real variable

The range of subjects presented and the consistency of style distinguished Lagrange's didactic writings from other contemporary expositions of the calculus. He began with Euler's notion of a function as an analytic expression composed of variables and constants. He defined the "derived function" or derivative $f'(x)$ of $f(x)$ to be the coefficient of i in the Taylor expansion of $f(x + i)$. Assuming the general possibility of such expansions, he attempted a rather complete theory of the differential and integral calculus, including extensive applications to geometry and mechanics. Lagrange's lectures represented the most advanced development of the 18th-century analytic conception of the calculus.

Beginning with Augustin-Louis Cauchy in the 1820s, later mathematicians used the concept of limit to establish the calculus on an arithmetic basis. The algebraic viewpoint of Euler and Lagrange was rejected. To arrive at a proper historical appreciation of their work it is necessary to reflect on the meaning of analysis in the 18th century. Since Viète, analysis had referred generally to mathematical methods that employed equations, variables, and constants. With the extensive development of the calculus by Leibniz and his school, analysis became identified with all calculus-related subjects. In addition to this historical association, there was a deeper sense in which analytic methods were fundamental to the new mathematics. An analytic equation implied the existence of a relation that remained valid as the variables changed continuously in magnitude. Analytic algorithms and transformations presupposed a correspondence between local and global change, the basic concern of the calculus. It is this aspect of analysis that fascinated Euler and Lagrange and caused them to see in it the "true metaphysics" of the calculus.

OTHER DEVELOPMENTS

During the period 1600–1800 significant advances occurred in the theory of equations, foundations of Euclidean geometry, number theory, projective geometry, and probability theory. These subjects, which became mature branches of mathematics only in the 19th century, never rivaled analysis and mechanics as programs of research.

Theory of equations. After the dramatic successes of Niccolò Fontana Tartaglia and Lodovico Ferrari in the 16th century the theory of equations developed slowly, as problems resisted solution by known techniques. In the later 18th century the subject experienced an infusion of new ideas. Interest was concentrated on two problems. The first was to establish the existence of a root of the general polynomial equation of degree n. The second was to express the roots as algebraic functions of the coefficients, or to show why it was not in general possible to do so.

The proposition that the general polynomial with real coefficients has a root of the form $a + b\sqrt{-1}$ became known later as the fundamental theorem of algebra. By 1742 Euler recognized that roots appear in conjugate pairs; if $a + b\sqrt{-1}$ is a root, then so is $a - b\sqrt{-1}$. Thus, if $a + b\sqrt{-1}$ is a root of $f(x) = 0$, then $f(x) = (x^2 - 2ax - a^2 - b^2)g(x)$. The fundamental theorem was therefore equivalent to asserting that a polynomial may be decomposed into linear and quadratic factors. This result was of considerable importance for the theory of integration, since by the method of partial fractions it ensured that a rational function, the quotient of two polynomials, could always be integrated in terms of algebraic and elementary transcendental functions.

The fundamental theorem of algebra

Although d'Alembert, Euler, and Lagrange worked on the fundamental theorem, the first successful proof was developed by Carl Friedrich Gauss in his doctoral dissertation of 1799. Earlier researchers had investigated special cases or had concentrated on showing that all possible roots were of the form $a \pm b\sqrt{-1}$. Gauss tackled the problem of existence directly. Expressing the unknown in terms of the polar variables r and θ, he showed that a solution of the polynomial would lie at the intersection of two curves of the form $T(r, \theta) = 0$ and $U(r, \theta) = 0$. By a careful and rigorous investigation he proved that the two curves intersect.

Gauss's demonstration of the fundamental theorem initiated a new approach to the question of mathematical existence. In the 18th century mathematicians were interested in the nature of particular analytic processes or the form that given solutions should take. Mathematical entities were regarded as things that were given, not as things whose existence needed to be established. Because analysis was applied in geometry and mechanics, the formalism seemed to possess a clear interpretation that obviated any need to consider questions of existence. Gauss's demonstration was the beginning of a change of attitude in mathematics, of a shift to the rigorous, internal development of the subject.

The problem of expressing the roots of a polynomial as functions of the coefficients was addressed by several mathematicians independently around 1770. The Cambridge mathematician Edward Waring published treatises in 1762 and 1770 on the theory of equations. In 1770 Lagrange presented a long expository memoir on the subject to the Berlin Academy, and in 1771 Alexandre Vandermonde submitted a paper to the French Academy of Sciences. Although the ideas of the three men were related, Lagrange's memoir was the most extensive and most influential historically.

Lagrange presented a detailed analysis of the solution by radicals of second-, third-, and fourth-degree equations and investigated why these solutions failed when the degree was greater than or equal to five. He introduced the novel idea of considering functions of the roots and examining the values they assumed as the roots were permuted. He was able to show that the solution of an equation depends on the construction of a second resolvent equation, but he was unable to provide a general procedure for solving the resolvent when the degree of the original equation was greater than four. Although his theory left the subject in an unfinished condition, it provided a solid basis for future work. The search for a general solution to the polynomial equation would provide the greatest single impetus for the transformation of algebra in the 19th century.

The efforts of Lagrange, Vandermonde, and Waring illustrate how difficult it was to develop new concepts in algebra. The history of the theory of equations belies the view that mathematics is subject to an almost automatic technical development. Much of the later algebraic work would be devoted to devising terminology, concepts, and methods necessary to advance the subject.

Foundations of geometry. Although the emphasis of mathematics after 1650 was increasingly on analysis, foundational questions in classical geometry continued to arouse interest. Attention centred on the fifth postulate of Book I of the *Elements,* which Euclid had used to prove the existence of a unique parallel through a point to a given line. Since antiquity, Greek, Islāmic, and European geometers had attempted unsuccessfully to show that the parallel postulate need not be a postulate but could instead be deduced from the other postulates of Euclidean geometry. During the period 1600–1800 mathematicians continued these efforts by trying to show that the postulate was equivalent to some result that was considered self-evident. Although the decisive breakthrough to non-Euclidean geometry would not occur until the 19th century, researchers did achieve a deeper and more systematic understanding of the classical properties of space.

The parallel postulate

Interest in the parallel postulate developed in the 16th century after the recovery and Latin translation of Proclus' commentary on Euclid's *Elements.* The Italian researchers Christopher Clavius in 1574 and Giordano Vitale in 1680 showed that the postulate is equivalent to asserting that the line equidistant from a straight line is a straight line. In 1693 John Wallis, Savilian professor of geometry at Oxford, attempted a different demonstration, proving that the axiom follows from the assumption that to every figure there exists a similar figure of arbitrary magnitude.

In 1733 the Italian Girolamo Saccheri published his *Euclides ab Omni Naevo Vindicatus* (*Euclid Cleared of Every Flaw*). This was an important work of synthesis in which he provided a complete analysis of the problem of parallels in terms of Omar Khayyam's quadrilateral. Using the Euclidean assumption that straight lines do not enclose an area, he was able to exclude geometries that contain no parallels. It remained to prove the existence of a unique parallel through a point to a given line. To do this Saccheri adopted the procedure of reductio ad absurdum; he assumed the existence of more than one parallel and attempted to derive a contradiction. After a long and detailed investigation, he was able to convince himself (mistakenly) that he had found the desired contradiction.

In 1766 Johann Heinrich Lambert of the Berlin Academy composed *Die Theorie der Parallellinien* ("The Theory of Parallel Lines"; published 1786), a penetrating study of the fifth postulate in Euclidean geometry. Among other theorems Lambert proved is that the parallel axiom is equivalent to the assertion that the sum of the angles of a triangle is equal to two right angles. He combined this fact with Wallis' result to arrive at an unexpected characterization of classical space. According to Lambert, if the parallel postulate is rejected, it follows that for every angle θ less than $2R/3$ (R is a right angle) an equilateral triangle can be constructed with corner angle θ. By Wallis' result any triangle similar to this triangle must be congruent to it. It is therefore possible to associate with every angle a definite length, the side of the corresponding equilateral triangle. Since the measurement of angles is absolute, independent of any convention concerning the selection of units, it follows that an absolute unit of length exists. Hence, to accept the parallel postulate is to deny the possibility of an absolute concept of length.

The final 18th-century contribution to the theory of parallels was Adrien-Marie Legendre's textbook *Éléments de géométrie,* the first edition of which appeared in 1794. Legendre presented an elegant demonstration that purported to show that the sum of the angles of a triangle is equal to two right angles. He believed that he had conclusively established the validity of the parallel postulate. His work attracted a large audience and was influential in informing readers of the new ideas in geometry.

The 18th-century failure to develop a non-Euclidean geometry was rooted in deeply held philosophical beliefs. In his *Critique of Pure Reason* (1781), Immanuel Kant had emphasized the synthetic a priori character of mathematical judgments. From this standpoint, statements of geometry and arithmetic were necessarily true propositions with definite empirical content. The existence of similar figures of different size, or the conventional character of units of length, appeared self-evident to mathematicians of the period. As late as 1824 Simon Laplace wrote:

The influence of Kant

> Thus the notion of space includes a special property, self-evident, without which the properties of parallels cannot be rigorously established. The idea of a bounded region, *e.g.,* the circle, contains nothing which depends on its absolute magnitude. But if we imagine its radius to diminish, we are brought without fail to the diminution in the same ratio of its circumference and the sides of all the inscribed figures. This proportionality appears to me a more natural postulate than that of Euclid, and it is worthy of note that it is discovered afresh in the results of the theory of universal gravitation.

Mathematics in the 19th and 20th centuries

Most of the powerful abstract mathematical theories in use today originated in the 19th century, so that any historical account of the period should be supplemented by reference to detailed treatments of these topics. Moreover, mathematics grew so much during this period that any account must necessarily be selective. Nonetheless, some broad features stand out. The growth of mathematics as a profession was accompanied by a sharpening division between mathematics and the physical sciences, and contact between the two subjects takes place today across a clear professional boundary. One result of this separation has been that mathematics, no longer able to rely on its scientific import for its validity, developed markedly higher standards of rigour. It was also freed to develop in directions that had little to do with applicability. Some of these pure creations have turned out to be surprisingly applicable, while the attention to rigour has led to a wholly novel conception of the nature of mathematics and logic. Moreover, many outstanding questions in mathematics yielded to the more conceptual approaches that came into vogue.

Projective geometry. The French Revolution provoked a radical rethinking of education in France, and mathematics was given a prominent role. The École Polytechnique was established in 1794 with the ambitious task of preparing all candidates for the specialist civil and military engineering schools of the republic. Mathematicians of the highest calibre were involved; the result was a rapid and sustained development of the subject. The inspiration for the École was that of Gaspard Monge, who believed strongly that mathematics should serve the scientific and technical needs of the state. To that end he devised a syllabus that promoted his own descriptive geometry, which was useful in the design of forts, gun emplacements, and machines and which was employed to great effect in the Napoleonic survey of Egyptian historical sites.

In Monge's descriptive geometry, three-dimensional objects are described by their orthogonal projections onto a horizontal and a vertical plane, the plan and elevation of the object. A pupil of Monge, Jean-Victor Poncelet, was taken prisoner in Napoleon's retreat from Moscow and sought to keep up his spirits while in jail in Saratov by thinking over the geometry he had learned. He dispensed with the restriction to orthogonal projections and decided to investigate what properties figures have in common with their shadows.

Poncelet

There are several of these properties: a straight line casts a straight shadow, and a tangent to a curve casts a shadow that is tangent to the shadow of the curve. But some properties are lost: the lengths and angles of a figure bear no relation to the lengths and angles of its shadow. Poncelet felt that the properties that survive are worthy of study, and, by considering only those properties that a figure shares with all its shadows, Poncelet hoped to put truly geometric reasoning on a par with algebraic geometry.

In 1822 Poncelet published the *Traité des propriétés projectives des figures* (*Treatise on the Projective Properties of Figures*). From his standpoint, every conic section is

equivalent to a circle, so his treatise contained a unified treatment of the theory of conic sections. It also established several new results. Geometers who took up his work divided into two groups: those who accepted his terms and those who, finding them obscure, reformulated his ideas in the spirit of algebraic geometry. On the algebraic side it was taken up in Germany by August Ferdinand Möbius, who seems to have come to his ideas independently of Poncelet, and then by Julius Plücker. They showed how rich was the projective geometry of curves defined by algebraic equations and thereby gave an enormous boost to the algebraic study of curves, comparable to the original impetus provided by Descartes. Germany also produced synthetic projective geometers, notably Jakob Steiner (born in Switzerland but educated in Germany) and Karl George Christian von Staudt, who emphasized what can be understood about a figure from a careful consideration of all its transformations.

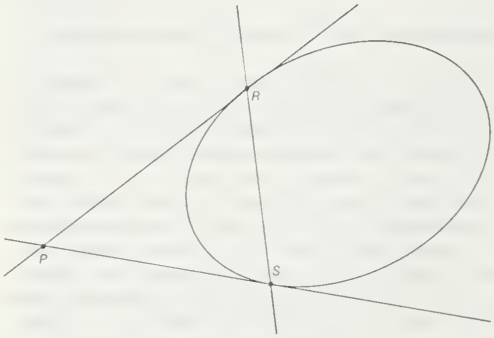

Figure 12: Duality associates with the point P the line RS, and vice versa.

Within the debates about projective geometry emerged one of the few synthetic ideas to be discovered since the days of Euclid, that of duality. This associates with each point a line and with each line a point, in such a way that (1) three points lying in a line give rise to three lines meeting in a point, and, conversely, three lines meeting in a point give rise to three points lying on a line, and (2) if one starts with a point (or a line) and passes to the associated line (point) and then repeats the process, one returns to the original point (line). One way of doing this (presented by Poncelet) is to pick an arbitrary conic and then to associate with a point P lying outside the conic the line that joins the points R and S at which the tangents through P to the conic touch the conic (see Figure 12). A second method is needed for points on or inside the conic. The feature of duality that makes it so exciting is that one can apply it mechanically to every proof in geometry, interchanging "point" and line" and "collinear" and "concurrent" throughout, and so obtain a new result. Sometimes a result turns out to be equivalent to the original, sometimes to its converse, but at a single stroke the number of theorems was more or less doubled.

Making the calculus rigorous. Monge's educational ideas were opposed by Lagrange, who favoured a more traditional and theoretical diet of advanced calculus and rational mechanics (the application of the calculus to the study of the motion of solids and liquids). Eventually Lagrange won, and the vision of mathematics that was presented to the world was that of an autonomous subject that was also applicable to a broad range of phenomena by virtue of its great generality, a view that has persisted to the present day.

During the 1820s Augustin-Louis Cauchy lectured at the École Polytechnique on the foundations of the calculus. Since its invention it had been generally agreed that the calculus gave correct answers, but no one had been able to give a satisfactory explanation of why this was so. Cauchy rejected Lagrange's algebraic approach and proved that Lagrange's basic assumption that every function had a power series expansion was in fact false. Newton had suggested a geometric or dynamic basis for calculus, but this ran the risk of introducing a vicious circle when the calculus was applied to mechanical or geometric problems. Cauchy proposed basing the calculus on a sophisticated and difficult interpretation of the idea of two points or numbers being arbitrarily close together. Although his students disliked the new approach, and Cauchy was ordered to teach material that the students could actually understand and use, his methods gradually became established and refined to form the core of the modern rigorous calculus, a subject now called mathematical analysis.

Mathematical analysis

Traditionally, the calculus had been concerned with the two processes of differentiation and integration and the reciprocal relation that exists between them. Cauchy provided a novel underpinning by stressing the importance of the concept of continuity, which is more basic than either. He showed that, once the concepts of a continuous function and limit are defined, the concepts of a differentiable function and an integrable function can be defined in terms of them. Unfortunately, neither of these concepts is easy to grasp, and the much-needed degree of precision they bring to mathematics has proved difficult to appreciate. Roughly speaking, a function is continuous at a point in its domain if small changes in the input around the specified value only produce small changes in the output.

Thus, in Figure 13 the familiar graph of a parabola $y = x^2$ is continuous around the point $x = 0$; as x varies by small amounts, so necessarily does y. On the other hand, the graph of the function that takes the value 0 when x is negative or zero, and the value 1 when x is positive, plainly has a discontinuous graph at the point $x = 0$, and it is indeed discontinuous there according to the definition. If x varies from 0 by any small positive amount, the value of the function jumps by the fixed amount 1, which is not an arbitrarily small amount.

Cauchy said that a function $f(x)$ tends to a limiting value l as x tends to the value a whenever the value of the difference $f(x) - f(a)$ becomes arbitrarily small as the difference $x - a$ itself becomes arbitrarily small. He then showed that, if $f(x)$ is continuous at a, the limiting value of the function as x tended to a was indeed $f(a)$. The crucial feature of this definition is that it defines what it means for a variable quantity to tend to something entirely without reference to ideas of motion.

Cauchy then said a function $f(x)$ is differentiable at the point a if, as x tends to a (which it is never allowed to reach), the value of the quotient $\{f(x) - f(a)\}/(x - a)$ tends to a limiting value, called the derivative of the function $f(x)$ at a. To define the integral of a function $f(x)$ between the values a and b, Cauchy went back to the primitive idea of integral as the measure of the area under the graph of the function. He approximated this area by rectangles and said that, if the sum of the areas of the rectangles tends to a limit as their number increases indefinitely and

Definition of the integral

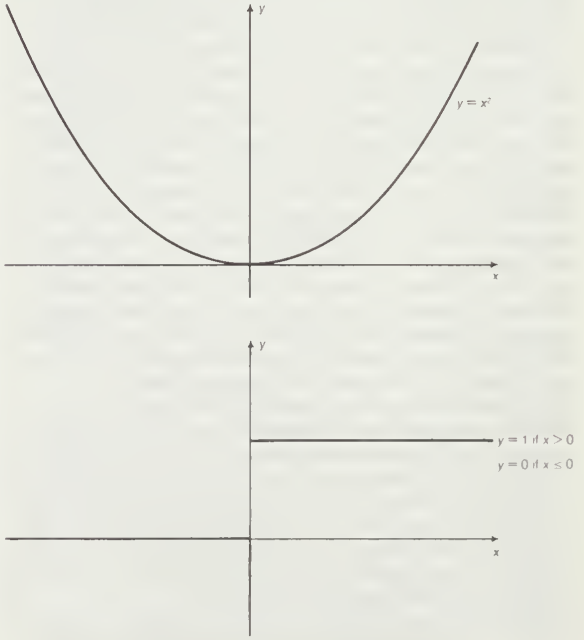

Figure 13: Continuous and discontinuous functions.

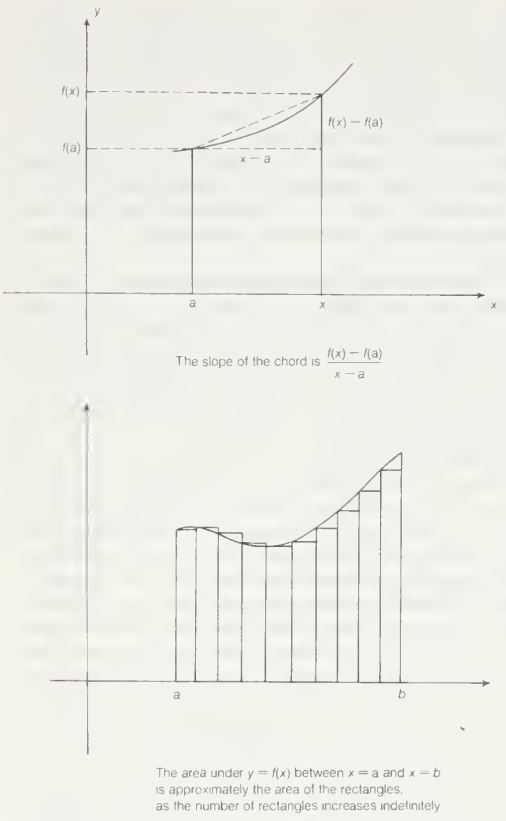

Figure 14: Differentiation and integration.

if this limiting value is the same however the rectangles are obtained, then the function is integrable. Its integral is the common limiting value. After he had defined the integral independently of the differential calculus, Cauchy had to prove that the processes of integrating and differentiating are mutually inverse. This he did, giving for the first time a rigorous foundation to all the elementary calculus of his day.

Fourier series. The other crucial figure of the time in France was Joseph Fourier. His major contribution, presented in *La Théorie analytique de la chaleur* (1822; *The Analytical Theory of Heat*), was to the theory of heat diffusion in solid bodies. He proposed that any function could be written as an infinite sum of the trigonometric functions cosine and sine, for example,

$$f(x) = a_0 + a_1 \sin x + a_2 \sin 2x + \ldots .$$

While expressions of this kind had been written down earlier, what was new in Fourier's treatment was the degree of attention given to their convergence. He investigated the question, "Given the function $f(x)$, for what range of values of x does the expression above sum to a finite number?" It turned out that the answer depends on the coefficients a_n, and Fourier gave rules for obtaining them of the form:

$$a_n = \int_{-\pi}^{\pi} f(x) \sin (nx) dx.$$

Had Fourier's work been entirely correct, it would have brought all functions into the calculus, making possible the solution of many kinds of differential equations and greatly extending the theory of mathematical physics. But his arguments were unduly naive: after Cauchy, it was not clear that the function $f(x) \sin (nx)$ was necessarily integrable. When Fourier's ideas were finally published, they were eagerly taken up, but the more cautious mathematicians, notably the influential German mathematician Peter Gustav Lejeune Dirichlet, wanted to rederive Fourier's conclusions in a more rigorous way. Fourier's methodology was widely accepted, but questions about its validity in detail were to occupy mathematicians for the rest of the century.

Elliptic functions. The theory of functions of a complex variable was also being decisively reformulated. At the start of the 19th century, complex numbers were discussed from a quasi-philosophical standpoint by several French writers, notably Jean Robert Argand. A consensus emerged that complex numbers should be thought of as pairs of real numbers, with suitable rules for their addition and multiplication so that the pair (0, 1) was a square root of -1. The underlying meaning of such a number pair was given by its geometric interpretation either as a point in a plane or as a directed segment joining the coordinate origin to the point in question. (This representation is sometimes called the Argand diagram.) In 1827, while revising an earlier manuscript for publication, Cauchy showed how the problem of integrating functions of two variables can be illuminated by a theory of functions of a single complex variable, which he was then developing. But the decisive influence on the growth of the subject came from the theory of elliptic functions.

The Argand diagram

The study of elliptic functions originated in the 18th century, when many authors studied integrals of the form

$$\int_0^x \frac{p(t)dt}{\sqrt{q(t)}},$$

where $p(t)$ and $q(t)$ are polynomials in t and $q(t)$ is of degree 3 or 4 in t. Such integrals arise naturally, for example, as an expression for the length of an arc of an ellipse (whence the name). These integrals cannot be evaluated explicitly; they do not define a function that can be obtained from the rational and trigonometric functions, a difficulty that added to their interest. Elliptic integrals were intensively studied for many years by the French mathematician Legendre, who was able to calculate tables of values for such expressions as functions of their upper endpoint, x. But the topic was completely transformed in the late 1820s by the independent but closely overlapping discoveries of two young mathematicians, the Norwegian Niels Henrik Abel and the German Carl Gustav Jacob Jacobi. These men showed that, if one allowed the variable x to be complex and the problem were inverted, so that the object of study became

$$u = \int_0^x \frac{p(t)dt}{\sqrt{q(t)}},$$

considered as defining a function x of a variable u, then a remarkable new theory could be discovered. The new function, for example, possessed a property that generalized the basic property of periodicity of the trigonometric functions sine and cosine: $\sin(x) = \sin(x + 2\pi)$. Any function of the kind just described has two distinct periods, ω_1 and ω_2:

$$x(u) = x(u + \omega_1) = x(u + \omega_2).$$

Elliptic functions

These new functions, the elliptic functions, aroused a considerable degree of interest from the first because many interesting and novel things could be said about them. The analogy with trigonometric functions ran very deep (indeed the trigonometric functions turned out to be special cases of elliptic functions), but their greatest influence was on the burgeoning general study of functions of a complex variable. The theory of elliptic functions became the paradigm of what could be discovered by allowing variables to be complex instead of real. But their natural generalization to functions defined by more complicated

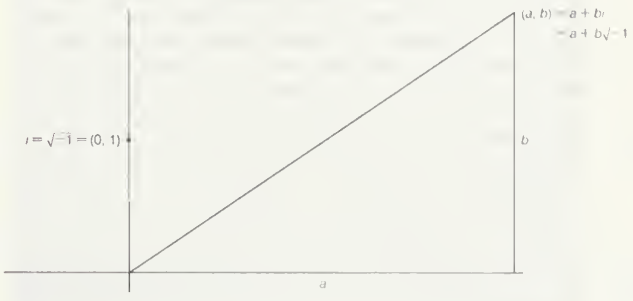

Figure 15: The plane of complex numbers (Argand diagram).

integrands, although it yielded partial results, resisted analysis until the second half of the 19th century.

The theory of numbers. While the theory of elliptic functions typifies the 19th century's enthusiasm for pure mathematics, some contemporary mathematicians said that the simultaneous developments in number theory carried that enthusiasm to excess. Nonetheless, during the 19th century the algebraic theory of numbers grew from being a minority interest to its present central importance in pure mathematics. The earlier investigations of Fermat had eventually drawn the attention of Euler and Lagrange. Euler proved some of Fermat's unproved claims and discovered many new and surprising facts; Lagrange not only supplied proofs of many remarks that Euler had merely conjectured but also worked them into something like a coherent theory. For example, it was known to Fermat that the numbers which can be written as the sum of two squares are either the number 2, squares themselves, primes of the form $4n + 1$, or else products of these numbers. Thus 29, which is $4 \times 7 + 1$, is $5^2 + 2^2$, but 35, which is not of this form, cannot be written as the sum of two squares. Euler had proved this result and had gone on to consider similar cases, such as primes of the form $x^2 + 2y^2$, or $x^2 + 3y^2$. But it was left to Lagrange to provide a general theory covering all expressions of the form $ax^2 + bxy + cy^2$, quadratic forms, as they are called.

Lagrange's theory of quadratic forms had made considerable use of the idea that a given quadratic form could often be simplified to another with the same properties but with smaller coefficients. To do this in practice, it was often necessary to consider whether a given integer left a remainder that was a square when it was divided by another given integer. (For example, 48 leaves a remainder of 4 upon division by 11, and 4 is a square.) Legendre discovered a remarkable connection between the question, "Does the integer p leave a square remainder on division by q?" and the seemingly unrelated question, "Does the integer q leave a square remainder upon division by p?" He saw, in fact, that, when p and q are primes, both questions have the same answer unless both primes are of the form $4n - 1$. Because this observation connects two questions in which the integers p and q play mutually opposite roles, it became known as the law of quadratic reciprocity. Legendre also gave an effective way of extending his law to cases when p and q are not prime.

All this work set the scene for the emergence of Gauss, whose *Disquisitiones Arithmeticae* not only consummated what had gone before but also directed number theorists in new and deeper directions. He rightly showed that Legendre's proof of the law of quadratic reciprocity was fundamentally flawed and gave the first rigorous proof. His work suggested that there were profound connections between the original question and other branches of number theory, a fact that he perceived to be of signal importance for the subject. He extended Lagrange's theory of quadratic forms by showing how two quadratic forms can be "multiplied" to obtain a third. Later mathematicians were to rework this into an important example of the theory of finite commutative groups. And in the long final section of his book Gauss gave the theory that lay behind his first discovery as a mathematician: that a regular 17-sided figure can be constructed by circle and straightedge alone.

The discovery that the regular "17-gon" is so constructible was the first such discovery since the Greeks, who had known only of the equilateral triangle, the square, the regular pentagon, the regular 15-sided figure, and the figures that can be obtained from these by successively bisecting all the sides. But what was of much greater significance than the discovery was the theory that underpinned it, the theory of what are now called algebraic numbers. It may be thought of as an analysis of how complicated a number may be while yet being amenable to an exact treatment.

The theory of algebraic numbers

The simplest numbers to understand and use are the integers and the rational numbers; the irrational numbers seem to pose problems. Famous among these is $\sqrt{2}$. It cannot be written as a finite or repeating decimal (because it is not rational), but it can be manipulated algebraically very easily. It is only necessary to replace every occurrence of $(\sqrt{2})^2$ by 2. In this way expressions of the form $m + n\sqrt{2}$, where m and n are integers, can be handled arithmetically. These expressions have many properties akin to those of whole numbers, and one can even define prime numbers of this form; therefore they are called algebraic integers. In this case they are obtained by grafting onto the rational numbers a solution of the polynomial equation $x^2 - 2 = 0$. In general an algebraic integer is any solution, real or complex, of a polynomial equation with integer coefficients in which the coefficient of the highest power of the unknown is 1.

Gauss's theory of algebraic integers led to the question of determining when a polynomial of degree n with integer coefficients can be solved given the solvability of polynomial equations of lower degree but with coefficients that are algebraic integers. For example, he regarded the coordinates of the 17 vertices of a regular 17-sided figure as complex numbers satisfying the equation $x^{17} - 1 = 0$, and thus as algebraic integers. One such integer is $z = 1$. He showed that the rest are obtained by solving a succession of four quadratic equations. Because solving a quadratic equation is equivalent to performing a construction with a ruler and compass, as Descartes had shown long before, Gauss had shown how to construct the regular 17-gon.

Inspired by Gauss's works on the theory of numbers, a growing school of mathematicians was drawn to the subject. Like Gauss, the German mathematician Ernst Eduard Kummer sought to generalize the law of quadratic reciprocity to deal with questions about third, fourth, and higher powers of numbers. He found that his work led him in an unexpected direction, toward a partial resolution of Fermat's last theorem. In 1637 Fermat wrote in the margin of his copy of Diophantus' *Arithmetica* the claim to have a proof that there are no solutions in positive integers to the equation $x^n + y^n = z^n$ if $n > 2$. However, no proof was ever discovered among his notebooks.

Kummer's approach was to develop the theory of algebraic integers. If it could be shown that the equation had no solution in suitable algebraic integers, then a fortiori there could be no solution in ordinary integers. He was eventually able to establish the truth of Fermat's last theorem for a large class of prime exponents n (those satisfying some technical conditions needed to make the proof work). This was the first significant breakthrough in the study of the theorem. Together with the earlier work of the French mathematician Sophie Germain, it has enabled mathematicians to establish Fermat's last theorem for every value of n from 3 to 4,000,000. However, Kummer's way around the difficulties he encountered further propelled the theory of algebraic integers into the realm of abstraction. It amounted to the suggestion that there should be yet other types of integers, but many found these ideas obscure.

The ideal algebraic integers

In Germany Richard Dedekind patiently created a new approach, in which each new number (called ideal) was defined by means of a suitable set of algebraic integers in such a way that it was the common divisor of the set of algebraic integers used to define it. Dedekind's work was slow to gain approval, yet it illustrates several of the most profound features of modern mathematics. It was clear to Dedekind that the ideal algebraic integers were the work of the human mind. Their existence can neither be based on nor deduced from the existence of physical objects, analogies with natural processes, or some process of abstraction from more familiar things. A second feature of Dedekind's work was its reliance on the idea of sets of objects, such as sets of numbers, even sets of sets. Dedekind's work showed how basic the naive conception of a set could be. The third crucial feature of his work was its emphasis on the structural aspects of algebra. The presentation of number theory as a theory about objects that can be manipulated (in this case, added and multiplied) according to certain rules akin to those governing ordinary numbers was to be a paradigm of the more formal theories of the 20th century.

The theory of equations. Another subject that was transformed in the 19th century was the theory of equations. Ever since Tartaglia and Ferrari in the 16th century had found rules giving the solutions of cubic and quartic

equations in terms of the coefficients of the equations. formulas had unsuccessfully been sought for equations of the fifth and higher degrees. At stake was the existence of a formula that expresses the roots of a quintic equation in terms of the coefficients. This formula moreover, must involve only the operations of addition, subtraction, multiplication, and division, together with the extraction of roots, since that was all that had been required for the solution of quadratic, cubic, and quartic equations. If such a formula were to exist, the quintic would accordingly be said to be solvable by radicals.

In 1770 Lagrange had analyzed all the successful methods he knew for equations of degrees 2, 3, and 4, in an attempt to see why they worked and how they could be generalized. His analysis of the problem in terms of permutations of the roots was promising, but he became more and more doubtful as the years went by that his complicated line of attack could be carried through. The first valid proof that the general quintic is not solvable by radicals was offered only after his death, in a startlingly short paper by Abel, written in 1824.

Abel also showed by example that some quintic equations were solvable by radicals and that some equations could be solved unexpectedly easily. For example, the equation $x^5 - 1 = 0$ has one root $x = 1$, but the remaining four roots can be found just by extracting square roots, not fourth roots as might be expected. He therefore raised the question, "What equations of degree higher than 4 are solvable by radicals?"

Abel died in 1829 at the age of 26 and did not resolve the problem he had posed. Almost at once, however, the astonishing prodigy Évariste Galois burst upon the Parisian mathematical scene. He submitted an account of his novel theory of equations to the Academy of Sciences in 1829, but the manuscript was lost. A second version was also lost and was not found among Fourier's papers when Fourier, the secretary of the academy, died in 1830. Galois was killed in a duel in 1832, at the age of 20, and it was not until his papers were published in Joseph Liouville's *Journal de mathématiques* in 1846 that his work began to receive the attention it deserved. His theory eventually made the theory of equations into a mere part of the theory of groups. Galois emphasized the group (as he called it) of permutations of the roots of an equation. This move took him away from the equations themselves, instead turning toward the markedly more tractable study of permutations. To any given equation there corresponds a definite group, with a definite collection of subgroups. To explain which equations were solvable by radicals and which were not, Galois analyzed the ways in which these subgroups were related to one another: solvable equations gave rise to what are now called a chain of normal subgroups with cyclic quotients. This technical condition makes it clear how far mathematicians had gone from the familiar questions of 18th-century mathematics, and it marks a transition characteristic of modern mathematics: the replacement of formal calculation by conceptual analysis. This is a luxury available to the pure mathematician that the applied mathematician faced with a concrete problem cannot always afford.

The theory of groups

According to this theory, a group is a set of objects that one can combine in pairs in such a way that the resulting object is also in the set. Moreover, this way of combination has to obey the following rules (here objects in the group are denoted *a, b,* etc., and the combination of *a* and *b* is written $a * b$):

1. There is an element, *e,* such that $a * e = a = e * a$ for every element *a* in the group. This element is called the identity element of the group.
2. For every element *a* there is an element, written a^{-1}, with the property that $a * a^{-1} = e = a^{-1} * a$. The element a^{-1} is called the inverse of *a*.
3. For every *a, b,* and *c* in the group the associative law holds: $(a * b) * c = a * (b * c)$.

Examples of groups include the integers with * interpreted as addition and the positive rational numbers with * interpreted as multiplication. An important property shared by some groups but not all is commutativity: for every element *a* and *b*, $a * b = b * a$. The rotations of an object in the plane around a fixed point form a commutative group, but the rotations of a three-dimensional object around a fixed point form a noncommutative group.

Gauss. A convenient way to assess the situation in mathematics in the mid-19th century is to look at the career of its greatest exponent, the last man to be called the "Prince of Mathematics," Carl Friedrich Gauss. In 1801, the same year in which he published his *Disquisitiones Arithmeticae,* he rediscovered the asteroid Ceres (which had disappeared behind the Sun not long after it had first been discovered and before its orbit was precisely known). He was the first to give a sound analysis of the method of least squares in the analysis of statistical data. Gauss did important work in potential theory and, with the German physicist Wilhelm Weber, built the first electric telegraph. He helped conduct the first survey of the Earth's magnetic field and did both theoretical and field work in cartography and surveying. He was a polymath who almost singlehandedly embraced what elsewhere was being put asunder: the world of science and the world of mathematics. It is his purely mathematical work, however, that in its day and ever since has been regarded as the best evidence of his genius.

Gauss's writings transformed the theory of numbers. His theory of algebraic integers lay close to the theory of equations as Galois was to redefine it. More remarkable are the extensive writings on the theory of elliptic functions dating from 1797 to the 1820s but unpublished at his death. In 1827 he published his crucial discovery that the curvature of a surface can be defined intrinsically—that is, solely in terms of properties defined within the surface and without reference to the surrounding Euclidean space. This result was to be decisive in the acceptance of non-Euclidean geometry. All his work displays a sharp concern for rigour and a refusal to rely on intuition or physical analogy, which was to serve as an inspiration to his successors. His emphasis on achieving full conceptual understanding, which may have led to his dislike of publication, was by no means the least influential of his achievements.

Gauss's work on the theory of elliptic functions

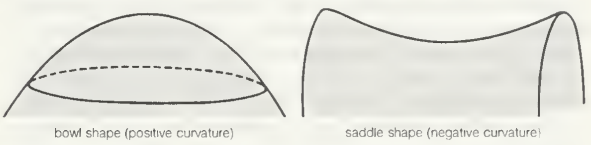

Figure 16: Intrinsic curvature of a surface.

Non-Euclidean geometry. Perhaps it was this desire for conceptual understanding that made Gauss reluctant to publish the fact that he was led more and more "to doubt the truth of geometry," as he put it. For if there was a logically consistent geometry differing from Euclid's only because it made a different assumption about the behaviour of parallel lines, it too could apply to physical space, and so the truth of (Euclidean) geometry could no longer be assured a priori, as Kant had thought.

Gauss's investigations into the new geometry went further than any one else's before him, but he did not publish them. The honour of being the first to proclaim the existence of a new geometry belongs to two others, who did so in the late 1820s: Nicolay Ivanovich Lobachevsky in Russia and János Bolyai in Hungary. Because the similarities in the work of these two men far exceed the differences, it is convenient to describe their work together.

Both men made an assumption about parallel lines that differed from Euclid's and proceeded to draw out its consequences. This way of working cannot guarantee the consistency of one's findings, so strictly speaking they could not prove the existence of a new geometry in this way. Both men described a three-dimensional space different from Euclidean space, couching their findings in the language of trigonometry. The formulas they obtained were exact analogues of the formulas that describe triangles drawn on the surface of a sphere, with the usual trigonometric functions replaced by those of hyperbolic trigonometry. (The functions hyperbolic cosine, written cosh, and hyperbolic sine, written sinh [see Figure 17], are defined as follows: $\cosh x = \frac{1}{2}(e^x + e^{-x})$, and $\sinh x = \frac{1}{2}(e^x - e^{-x})$. They are called hyperbolic because of their use in describ-

The hyperbolic functions

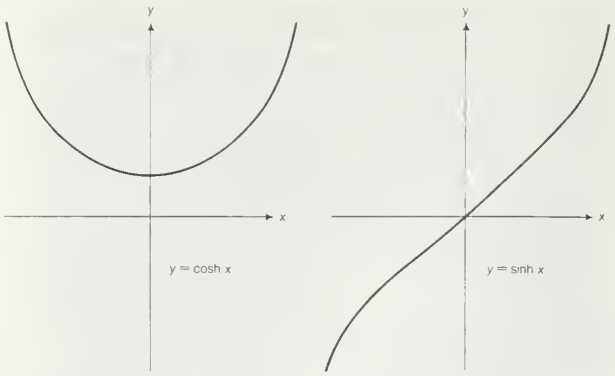

Figure 17: The hyperbolic functions cosh x and sinh x.

ing the hyperbola. Their names derive from the evident analogy with the trigonometric functions, which Euler showed satisfy these equations: $\cos x = \frac{1}{2}\{e^{ix} + e^{-ix}\}$, and $\sin x = (\frac{1}{2}i)\{e^{ix} - e^{-ix}\}$.) The formulas were what gave their work the precision needed to give conviction in the absence of a sound logical structure. Both men observed that it had become an empirical matter to determine the nature of space, Lobachevsky even going so far as to conduct astronomical observations, although these proved inconclusive.

The work of Bolyai and Lobachevsky was poorly received. Gauss endorsed what they had done, but so discreetly that most mathematicians did not find out his true opinion on the subject until he was dead. The main obstacle each man faced was surely the shocking nature of their discovery. It was easier, and in keeping with 2,000 years of tradition, to continue to believe that Euclidean geometry was correct and that Bolyai and Lobachevsky had somewhere gone astray, like many an investigator before them.

The turn toward acceptance came in the 1860s after Bolyai and Lobachevsky had died. The Italian mathematician Eugenio Beltrami decided to investigate Lobachevsky's work and to place it, if possible, within the context of differential geometry as redefined by Gauss. He therefore moved independently in the direction already taken by Bernhard Riemann. He investigated the surface of constant negative curvature and found that on such a surface triangles obeyed the formulas of hyperbolic trigonometry that Lobachevsky had discovered were appropriate to his form of non-Euclidean geometry. Thus he gave the first rigorous description of a geometry other than Euclid's. Beltrami's account of the surface of constant negative curvature was ingenious. He said that it was an abstract surface which he could describe by drawing maps of it, much as one might describe a sphere by means of the pages of a geographic atlas. He did not claim to have constructed the surface embedded in Euclidean three-dimensional space; later Hilbert showed that it cannot be done.

Riemann. When Gauss died in 1855, his post at Göttingen was taken by Peter Gustav Lejeune Dirichlet. One mathematician who found the presence of Dirichlet a stimulus to research was Riemann, and his few short contributions to mathematics were among the most influential of the century. Riemann's first paper, his doctoral thesis (1851) on the theory of complex functions, provided the foundations for a geometric treatment of functions of a complex variable. His main result guaranteed the existence of a wide class of complex functions satisfying only modest general requirements and so made it clear that complex functions could be expected to occur widely in mathematics. More importantly, it was achieved by yoking together the complex theory with the theory of harmonic functions and potential theory. The theories of complex and harmonic functions were henceforth inseparable.

Riemann then wrote on the theory of Fourier series and their integrability. His paper was directly in the tradition that ran from Cauchy and Fourier to Dirichlet, and it marked a considerable step forward in the precision with which the concept of integral can be defined. In 1854 he took up a subject that much interested Gauss, the hypotheses lying at the basis of geometry.

The study of geometry has always been one of the central concerns of mathematicians. It was the language, and the principal subject matter, of Greek mathematics, the mainstay of elementary education in the subject, and it has an obvious visual appeal. It seems easy to apply, for one can proceed from a base of naively intelligible concepts. In keeping with the general trends of the century, however, it was just the naive concepts that Riemann chose to refine. What he proposed as the basis of geometry was far more radical and fundamental than anything that had gone before.

Riemann's work on the foundations of geometry

Riemann took his inspiration from Gauss's discovery that the curvature of a surface is intrinsic, and he argued that one should therefore ignore Euclidean space and treat each surface by itself. A geometric property, he argued, was one that was intrinsic to the surface. To do geometry, it was enough to be given a set of points and a way of measuring lengths along curves in the surface. For this, traditional ways of applying the calculus to the study of curves could be made to suffice. But Riemann did not stop with surfaces. He proposed that geometers study spaces of any dimension in this spirit, even, he said, spaces of infinite dimension.

Several profound consequences followed from this view. It dethroned Euclidean geometry, which now became just one of many geometries. It allowed the geometry of Bolyai and Lobachevsky to be recognized as the geometry of a surface of constant negative curvature, thus resolving doubts about the logical consistency of their work. It highlighted the importance of intrinsic concepts in geometry. It helped open the way to the study of spaces of many dimensions. Last, but not least, Riemann's work ensured that any investigation of the geometric nature of physical space would thereafter have to be partly empirical. One could no longer say that physical space is Euclidean because there is no geometry but Euclid's. This finally destroyed any hope that questions about the world could be answered by a priori reasoning.

In 1857 Riemann published several papers applying his very general methods for the study of complex functions to various parts of mathematics. One of these papers solved the outstanding problem of extending the theory of elliptic functions to the integration of any algebraic function. It opened up the theory of complex functions of several variables and showed how Riemann's novel topological ideas were essential in the study of complex functions. (In subsequent lectures Riemann showed how the special case of the theory of elliptic functions could be regarded as the study of complex functions on a torus.)

Another paper dealt with the question of how many prime numbers there are that are less than any given number x. The answer is a function of x, and Gauss had conjectured on the basis of extensive numerical evidence that this function was approximately $x/\ln(x)$. This turned out to be true, but it was not proved until 1896, when both the Belgian mathematician Charles Jean de la Vallée-Poussin and the French mathematician Jacques-Salomon Hadamard independently proved it. It is remarkable that a question about integers led to a discussion of functions of a complex variable, but similar connections had previously been made by Dirichlet. Riemann took the expression $\Pi(1 - p^{-s})^{-1} = \Sigma n^{-s}$, introduced by Euler the century before, where the infinite product is taken over all prime numbers p and the sum over all whole numbers n and treated it as a function of s. The infinite sum makes sense whenever s is real and greater than 1. Riemann proceeded to study this function when s is complex (now called the Riemann zeta function), and he thereby not only helped clarify the question of the distribution of primes but also was led to several other remarks that later mathematicians were to find of exceptional interest. One remark has continued to elude proof and remains one of the greatest conjectures in mathematics: the claim that the nonreal zeros of the zeta function are complex numbers whose real part is always equal to $\frac{1}{2}$.

The Riemann zeta function

Riemann's influence. In 1859 Dirichlet died and Riemann became a full professor, but he was already ill with tuberculosis, and in 1862 his health broke. He died in 1866. His work, however, exercised a growing influence

on his successors. His work on trigonometric series, for example, led to a deepening investigation of the question of when a function is integrable. Attention was concentrated on the nature of the sets of points at which functions and their integrals (when these existed) had unexpected properties. The conclusions that emerged were at first obscure, but it became clear that some properties of point sets were important in the theory of integration, while others were not. (These other properties proved to be a vital part of the emerging subject of topology.) The properties of point sets that matter in integration have to do with the size of the set. If one can change the values of a function on a set of points without changing its integral, it is said that the set is of negligible size. The naive idea is that integrating is a generalization of counting: negligible sets do not need to be counted. Around the turn of the century the French mathematician Henri-Léon Lebesgue managed to systematize this naive idea into a new theory about the size of sets, which included integration as a special case. In this theory, called measure theory, there are sets that can be measured, and they either have positive measure or are negligible (they have zero measure), and there are sets that cannot be measured at all.

The first success for Lebesgue's theory was that, unlike the Cauchy–Riemann integral, it obeyed the rule that, if a sequence of functions $f_n(x)$ tended suitably to a function $f(x)$, then the sequence of integrals $\int f_n(x)dx$ tended to the integral $\int f(x)dx$. This has made it the natural theory of the integral when dealing with questions about trigonometric series. Another advantage is that it is very general. For example, in probability theory it is desirable to estimate the likelihood of certain outcomes of an experiment. By imposing a measure on the space of all possible outcomes, the Russian mathematician Andrey Kolmogorov was the first to put probability theory on a rigorous mathematical footing.

Another example is provided by a remarkable result discovered by the 20th-century American mathematician Norbert Wiener: within the set of all continuous functions on an interval, the set of differentiable functions has measure zero. In probabilistic terms, therefore, the chance that a function taken at random is differentiable has probability zero. In physical terms, this means that, for example, a particle moving under Brownian motion almost certainly is moving on a nondifferentiable path. This discovery clarified Einstein's fundamental ideas about Brownian motion (displayed by the continual motion of specks of dust in a fluid under the constant bombardment of surrounding molecules). The hope of physicists is that Richard Feynman's theory of quantum electrodynamics will yield to a similar measure-theoretic treatment, for it has the disturbing aspect of a theory that has not been made rigorous mathematically but that accords excellently with observation.

Applications of measure theory

Yet another setting for Lebesgue's ideas was to be the theory of Lie groups. The Hungarian mathematician Alfréd Haar showed how to define the concept of measure so that functions defined on Lie groups could be integrated. This became a crucial part of Hermann Weyl's way of representing a Lie group as acting linearly on the space of all (suitable) functions on the group (for technical reasons, "suitable" means that the square of the function is integrable with respect to a Haar measure on the group).

Differential equations. Another field that developed considerably in the 19th century was the theory of differential equations. The pioneer in this direction once again was Cauchy. Above all, he insisted that one should prove that solutions do indeed exist; it is not a priori obvious that every ordinary differential equation has solutions. The methods that Cauchy proposed for these problems fitted naturally into his program of providing rigorous foundations for all the calculus. The solution method he preferred, although the less general of his two approaches, worked equally well in the real and complex cases. It established the existence of a solution equal to the one obtainable by traditional power series methods using newly developed techniques in his theory of functions of a complex variable.

The harder part of the theory of differential equations concerns partial differential equations, those for which the unknown function is a function of several variables. In the early 19th century there was no known method of proving that a given second- or higher-order partial differential equation had a solution, and there was not even a method of writing down a plausible candidate. In this case progress was to be much less marked. Cauchy found new and more rigorous methods for first-order partial differential equations, but the general case eluded treatment.

An important special case was successfully prosecuted, that of dynamics. Dynamics is the study of the motion of a physical system under the action of forces. Working independently of each other, William Rowan Hamilton in Ireland and Jacobi in Germany showed how problems in dynamics could be reduced to systems of first-order partial differential equations. From this base grew an extensive study of certain partial differential operators. These are straightforward generalizations of a single partial differentiation $(\partial/\partial x)$ to a sum of the form

$$a_1\frac{\partial}{\partial x_1}+\ldots+a_n\frac{\partial}{\partial x_n},$$

where the a's are functions of the x's. The effect of performing several of these in succession can be complicated, but Jacobi and the other pioneers in this field found that there are formal rules which such operators tend to satisfy. This enabled them to shift attention to these formal rules, and gradually an algebraic analysis of this branch of mathematics began to emerge.

The most influential worker in this direction was the Norwegian, Sophus Lie. Lie, and independently Wilhelm Killing in Germany, came to suspect that the systems of partial differential operators they were studying came in a limited variety of types. Once the number of independent variables was specified (which fixed the dimension of the system), a large class of examples, including many of considerable geometric significance, seemed to fall into a small number of patterns. This suggested that the systems could be classified, and such a prospect naturally excited mathematicians. After much work by Lie and Killing and later by the French mathematician Élie-Joseph Cartan, they were classified. Initially, this discovery aroused interest because it produced order where previously the complexity had threatened chaos and because it could be made to make sense geometrically. The realization that there were to be major implications of this work for the study of physics lay well in the future.

The classification of systems of partial differential operators

Linear algebra. Differential equations, whether ordinary or partial, may profitably be classified as linear or nonlinear; linear differential equations are those for which the sum of two solutions is again a solution. The equation giving the shape of a vibrating string is linear, which provides the mathematical reason why a string may simultaneously emit more than one frequency. The linearity of an equation makes it easy to find all its solutions, so in general linear problems have been tackled successfully, while nonlinear equations continue to be difficult. Indeed, in many linear problems there can be found a finite family of solutions with the property that any solution is a sum of them (suitably multiplied by arbitrary constants). Obtaining such a family, called a basis, and putting them into their simplest and most useful form, was an important source of many techniques in the field of linear algebra.

Consider, for example, the system of linear differential equations

$$\frac{dy_1}{dx}=ay_1+by_2,\quad \frac{dy_2}{dx}=cy_1+dy_2.$$

It is evidently much more difficult to study than the system $dy_1/dx=\alpha y_1$, $dy_2/dx=\beta y_2$, whose solutions are (constant multiples of) $y_1=\exp(\alpha x)$ and $y_2=\exp(\beta x)$. But if a suitable linear combination of y_1 and y_2 can be found so that the first system reduces to the second, then it is enough to solve the second system. The existence of such a reduction is determined by the array (called a matrix) of the four numbers $\begin{bmatrix} a & b \\ c & d \end{bmatrix}$. In 1858 the English mathematician Arthur

Cayley began the study of matrices in their own right when he noticed that they satisfy polynomial equations. The matrix $A = \begin{bmatrix} a & b \\ c & d \end{bmatrix}$, for example, satisfies the equation $A^2 - (a+d)A + (ad - bc) = 0$. Moreover, if this equation has two distinct roots, say, α and β, then the sought-for reduction will exist and the coefficients of the simpler system will indeed be those roots α and β. If the equation has a repeated root, then the reduction usually cannot be carried out. In either case the difficult part of solving the original differential equation has been reduced to elementary algebra.

Vector spaces

The study of linear algebra begun by Cayley and continued by Leopold Kronecker includes a powerful theory of vector spaces. These are sets whose elements can be added together and multiplied by arbitrary numbers, such as the family of solutions of a linear differential equation. A more familiar example is that of three-dimensional space. If one picks an origin, then every point in space can be labeled by the line segment (called a "vector") joining it to the origin. Matrices appear as ways of representing linear transformations of a vector space—*i.e.*, transformations that preserve sums and multiplication by numbers: the transformation T is linear if, for any vectors $\boldsymbol{u}$, $\boldsymbol{v}$, $T(\boldsymbol{u} + \boldsymbol{v}) = T(\boldsymbol{u}) + T(\boldsymbol{v})$ and, for any scalar λ, $T(\lambda \boldsymbol{v}) = \lambda T(\boldsymbol{v})$. When the vector space is finite-dimensional, linear algebra and geometry form a potent combination. Vector spaces of infinite dimensions also are studied.

The theory of vector spaces is useful in other ways. Vectors in three-dimensional space represent such physically important concepts as velocities and forces. Such an assignment of vector to point is called a vector field; examples include electric and magnetic fields. Scientists such as Maxwell and J. Willard Gibbs took up vector analysis and were able to extend vector methods to the calculus. They introduced in this way measures of how a vector field varies infinitesimally, which, under the names div, grad, and curl, have become the standard tools in the study of electromagnetism and potential theory. To the modern mathematician, div, grad, and curl form part of a theory to which Stokes's theorem (a special case of which is Green's theorem) is central. This result, named after two leading English applied mathematicians of the 19th century, generalizes the fundamental theorem of the calculus to functions of several variables. The fundamental theorem asserts that

$$\int_a^b f'(x) = f(b) - f(a),$$

which can be read as saying that the integral of the derivative of some function in an interval is equal to the difference in the values of the function at the endpoints of the interval. Generalized to a part of a surface or space, this asserts that the integral of the derivative of some function over a region is equal to the integral of the function over the boundary of the region. In symbols this says that $\int d\omega = \int \omega$, where the first integral is taken over the region in question and the second integral over its boundary, while $d\omega$ is the derivative of ω.

The foundations of geometry. By the late 19th century the hegemony of Euclidean geometry had been challenged by non-Euclidean geometry and projective geometry. The first notable attempt to reorganize the study of geometry was made by the German mathematician Felix Klein and published at Erlangen in 1872. In his *Erlanger Programm* Klein proposed that Euclidean and non-Euclidean geometry be regarded as special cases of projective geometry. In each case the common features that, in Klein's opinion, made them geometries were that there was a set of points, called a "space," and a group of transformations by means of which figures could be moved around in the space without altering their essential properties. For example, in Euclidean plane geometry the space is the familiar plane, and the transformations are rotations, reflections, translations, and their composites, none of which change either length or angle, the basic properties of figures in Euclidean geometry. Different geometries would have different spaces and different groups, and the figures would have different basic properties.

The *Erlanger Programm*

Klein produced an account that unified a large class of geometries, roughly speaking all those which were homogeneous in the sense that every piece of the space looked like every other piece of the space. This excluded, for example, geometries on surfaces of variable curvature, but it produced an attractive package for the rest and gratified the intuition of those who felt that somehow projective geometry was basic. It continued to look like the right approach when Lie's ideas appeared and there seemed to be a good connection between Lie's classification and the types of geometry organized by Klein.

Mathematicians could now ask why they had believed Euclidean geometry to be the only one when, in fact, many different geometries existed. The first to take up this question successfully was the German mathematician Moritz Pasch, who argued in 1882 that the mistake had been to rely too heavily on physical intuition. In his view an argument in mathematics should depend for its validity not on the physical interpretation of the terms involved but upon purely formal criteria. Indeed, the principle of duality did violence to the sense of geometry as a formalization of what one believed about (physical) points and lines; one did not believe that these terms were interchangeable.

The ideas of Pasch caught the attention of the German mathematician David Hilbert, who, with the French mathematician Henri Poincaré, came to dominate mathematics at the turn of the century. In wondering why it was that mathematics—and in particular geometry—produced correct results, he came to feel increasingly that it was not because of the lucidity of its definitions. Rather, mathematics worked because its (elementary) terms were meaningless. What kept it heading in the right direction was its rules of inference. Proofs were valid because they were constructed through the application of the rules of inference, according to which new assertions could be declared to be true simply because they could be derived, by means of these rules, from the axioms or previously proved theorems. The theorems and axioms were viewed as formal statements that expressed the relationships between these terms.

The rules governing the use of mathematical terms were arbitrary, Hilbert argued, and each mathematician could choose them at will, provided only that the choices made were self-consistent. A mathematician produced abstract systems unconstrained by the needs of science, and, if scientists found an abstract system that fit one of their concerns, they could apply the system secure in the knowledge that it was logically consistent.

The axiomatization of geometry

Hilbert first became excited about this point of view (presented in his *Grundlagen der Geometrie* ["Foundations of Geometry"], 1899) when he saw that it led not merely to a clear way of sorting out the geometries in Klein's hierarchy according to the different axiom systems they obeyed but to new geometries as well. For the first time there was a way of discussing geometry that lay beyond even the very general terms proposed by Riemann. Not all of these geometries have continued to be of interest, but the general moral that Hilbert first drew for geometry he was shortly to draw for the whole of mathematics.

The foundations of mathematics. By the late 19th century the debates about the foundations of geometry had become the focus for a running debate about the nature of the branches of mathematics. Cauchy's work on the foundations of the calculus, completed by the German mathematician Karl Weierstrass in the late 1870s, left an edifice that rested on concepts such as that of the natural number (the integers 1, 2, 3, and so on) and on certain constructions involving them. The algebraic theory of numbers and the transformed theory of equations had focused attention on abstract structures in mathematics. Questions that had been raised about numbers since Babylonian times turned out to be best cast theoretically in terms of entirely modern creations whose independence from the physical world was beyond dispute. Finally, geometry, far from being a kind of abstract physics, was now seen as dealing with meaningless terms obeying arbitrary systems of rules. Although there had been no conscious

plan leading in that direction, the stage was set for a consideration of questions about the fundamental nature of mathematics.

Similar currents were at work in the study of logic, which had also enjoyed a revival during the 19th century. The work of the English mathematician George Boole and the American Charles Sanders Peirce had contributed to the development of a symbolism adequate to explore all elementary logical deductions. Significantly, Boole's book on the subject was called *An Investigation of the Laws of Thought, on Which Are Founded the Mathematical Theories of Logic and Probabilities* (1854). In Germany, the logician Gottlob Frege had directed keen attention to such fundamental questions as what it means to define something and what sorts of purported definitions actually do define.

Cantor. All of these debates came together through the pioneering work of the German mathematician Georg Cantor on the concept of a set. Cantor had begun work in this area because of his interest in Riemann's theory of trigonometric series, but the problem of what characterized the set of all real numbers came to occupy him more and more. He began to discover unexpected properties of sets. For example, he could show that the set of all algebraic numbers, and a fortiori the set of all rational numbers, is countable in the sense that there is a one-to-one correspondence between the integers and the members of each of these sets by means of which for any member of the set of algebraic numbers (or rationals), no matter how large, there is always a unique integer it may be placed in correspondence with. But, more surprisingly, he could also show that the set of all real numbers is not countable. So, although the set of all integers and the set of all real numbers are both infinite, the set of all real numbers is a strictly larger infinity. This was in complete contrast to the prevailing orthodoxy, which proclaimed that infinite could only mean "larger than any finite amount."

Set theory

Here the concept of number was being extended and undermined at the same time. The concept was extended because it was now possible to count and order sets that the set of integers was too small to measure; and it was undermined because even the integers ceased to be basic undefined objects. Cantor himself had given a way of defining real numbers as certain infinite sets of rational numbers. Rational numbers were easy to define in terms of the integers, but now integers could be defined by means of sets. One way was given by Frege in *Die Grundlagen der Arithmetik* (1884). He regarded two sets as the same if they contained the same elements. So in his opinion there was only one empty set (today symbolized by Ø), the set with no members. A second set could be defined as having only one element by letting that element be the empty set itself (symbolized by {Ø}), a set with two elements by letting them be the two sets just defined (*i.e.*, {Ø, {Ø}}), and so on. Having thus defined the integers in terms of the primitive concepts "set" and "element of," Frege agreed with Cantor that there was no logical reason to stop, and he went on to define infinite sets in the same way Cantor had. Indeed, Frege was clearer than Cantor about what sets and their elements actually were.

Frege's proposals went in the direction of a reduction of all mathematics to logic. He hoped that every mathematical term could be defined precisely and manipulated according to agreed, logical rules of inference. This, the "logicist" program, was dealt an unexpected blow by the English mathematician and philosopher Bertrand Russell in 1902, who pointed out unexpected complications with the naive concept of a set. Nothing seemed to preclude the possibility that some sets were elements of themselves while others were not, but asked Russell, "what then of the set of all sets that were not elements of themselves?" If it is an element of itself, then it is not (an element of itself), but, if it is not, then it is—a paradox. Either the idea of a set as an arbitrary collection of already defined objects was flawed, or else the idea that one could legitimately form the set of all sets of a given kind was incorrect. Frege's program never recovered from this blow, and the theories of Russell, which he developed together with Alfred North Whitehead in their *Principia Mathematica* (1910–13), that went in the same direction never found lasting appeal with mathematicians.

Greater interest attached to the ideas that Hilbert and his school began to advance. It seemed to them that what had worked once for geometry could work again for all of mathematics. Rather than attempt to define things so that problems could not arise, they suggested that it was possible to dispense with definitions and cast all of mathematics in an axiomatic structure using the ideas of set theory. Indeed, the hope was that the study of logic could be embraced in this spirit, thus making logic a branch of mathematics, the opposite of Frege's intention. There was considerable progress in this direction, and there emerged both a powerful school of mathematical logicians (notably in Poland) and an axiomatic theory of sets that avoided Russell's paradoxes and the others which had sprung up.

The axiomatic school

In the 1920s Hilbert put forward his most detailed proposal for establishing the validity of mathematics. According to his theory of proofs, everything was to be put into an axiomatic form, allowing the rules of inference to be only those of elementary logic, and only those conclusions that could be reached from this finite set of axioms and rules of inference were to be admitted. He proposed that a satisfactory system would be one which was consistent, complete, and decidable. By consistent Hilbert meant that it should be impossible to derive both a statement and its negation; by complete, that every properly written statement should be such that either it or its negation was derivable from the axioms; by decidable, that one should have an algorithm which determines of any given statement whether it or its negation is provable. Such systems did exist, for example, the first-order predicate calculus, but none had been found capable of allowing mathematicians to do interesting mathematics.

Hilbert's program, however, did not last long. In 1931 the Austrian-born American mathematician and logician Kurt Gödel showed that there was no system of Hilbert's type within which the integers could be defined and which was both consistent and complete. Later Gödel and, independently, the English mathematician Alan Turing showed that decidability was also unattainable. Perhaps paradoxically, the effect of this dramatic discovery was to alienate mathematicians from the whole debate. Instead, mathematicians, who may not have been too unhappy with the idea that there is no way of deciding the truth of a proposition automatically, learned to live with the idea that not even mathematics rests on rigorous foundations. Progress since has been in other directions. An alternative axiom system for set theory was later put forward by the Hungarian-born American mathematician John von Neumann, which he hoped would help resolve contemporary problems in quantum mechanics. There was also a renewal of interest in statements that are both interesting mathematically and independent of the axiom system in use. The first of these was the American mathematician Paul Cohen's surprising resolution in 1963 of the continuum hypothesis, which was Cantor's conjecture that the set of all subsets of the rational numbers was of the same size as the set of all real numbers. This turns out to be independent of the usual axioms for set theory, so there are set theories (and therefore types of mathematics) in which it is true and others in which it is false.

The continuum hypothesis

Mathematical physics. At the same time that mathematicians were attempting to put their own house in order, they were also looking with renewed interest at contemporary work in physics. The man who did the most to rekindle their interest was Poincaré. Poincaré showed that dynamic systems described by quite simple differential equations, such as the solar system, can nonetheless yield the most random-looking, chaotic behaviour. He went on to explore ways in which mathematicians can nonetheless say things about this chaotic behaviour and so pioneered the way in which probabilistic statements about dynamic systems can be found to describe what otherwise defies our intelligence.

Poincaré later turned to problems of electrodynamics. After many years' work, the Dutch physicist Hendrik Antoon Lorentz had been led to an apparent dependence of length and time on motion, and Poincaré was pleased to notice

that the transformations that Lorentz proposed as a way of converting one observer's data into another's formed a group. This appealed to Poincaré and strengthened his belief that there was no sense in a concept of absolute motion; all motion was relative. Poincaré thereupon gave an elegant mathematical formulation of Lorentz's ideas, which fitted them into a theory in which the motion of the electron is governed by Maxwell's equations. Poincaré, however, stopped short of denying the reality of the ether or of proclaiming that the velocity of light is the same for all observers, so credit for the first truly relativistic theory of the motion of the electron rests with Einstein and his special theory of relativity (1905).

Einstein's special theory is so called because it treats only the special case of uniform relative motion. The much more important case of accelerated motion and motion in a gravitational field was to take a further decade and to require a far more substantial dose of mathematics. Einstein only changed his estimate of the value of pure mathematics, which he had hitherto disdained, when he discovered that many of the questions he was led to had already been formulated mathematically and had been solved. He was most struck by theories derived from the study of geometry in the sense in which Riemann had formulated it.

By 1915 a number of mathematicians were interested in reapplying their discoveries to physics. The leading institution in this respect was the University of Göttingen, where Hilbert had unsuccessfully attempted to produce a general theory of relativity before Einstein, and it was there that many of the leaders of the coming revolution in quantum mechanics were to study. There, too, went many of the leading mathematicians of their generation, notably John von Neumann and Hermann Weyl, to study with Hilbert. In 1904 Hilbert had turned to the study of integral equations. These arise in many problems where the unknown is itself a function of some variable, and especially in those parts of physics that are expressed in terms of extremal principles (such as the principle of least action). The extremal principle usually yields information about an integral involving the sought-for function, hence the name "integral equation." Hilbert's contribution was to bring together many different strands of contemporary work and to show how they could be elucidated if cast in the form of arguments about objects in certain infinite-dimensional vector spaces.

Integral equations

The extension to infinite dimensions was not a trivial task, but it brought with it the opportunity to use geometric intuition and geometric concepts to analyze problems about integral equations. Hilbert left it to his students to provide the best abstract setting for his work, and thus was born the concept of a Hilbert space. Roughly speaking this is an infinite-dimensional vector space in which it makes sense to speak of the lengths of vectors and the angles between them; useful examples include certain spaces of sequences and certain spaces of functions. Operators defined on these spaces are also of great interest; their study forms part of the field of functional analysis.

When in the 1920s mathematicians and physicists were seeking ways to formulate the new quantum mechanics, von Neumann proposed that the subject be written in the language of functional analysis. The quantum mechanical world of states and observables, with its mysterious wave packets that were sometimes like particles and sometimes like waves depending on how they were observed, went very neatly into the theory of Hilbert spaces. Functional analysis has ever since grown with the fortunes of particle physics.

Algebraic topology. The early 20th century saw the emergence of a number of theories whose power and utility reside in large part in their generality. Typically, they are marked by an attention to the set or space of all examples of a particular kind. (Functional analysis is such an endeavour.) One of the most energetic of these general theories was that of algebraic topology. In this subject a variety of ways are developed for replacing a space by a group and a map between spaces by a map between groups. It is like using X rays: information is lost, but the shadowy image of the original space may turn out to contain, in an accessible form, enough information to solve the question at hand.

Interest in this kind of research came from various directions. Galois's theory of equations was an example of what could be achieved by transforming a problem in one branch of mathematics into a problem in another, more abstract branch. Another impetus came from Riemann's theory of complex functions. He had studied algebraic functions, that is, loci defined by equations of the form $f(x, y) = 0$, where f is a polynomial in x whose coefficients are polynomials in y. When x and y are complex variables, the locus can be thought of as a real surface spread out over the x plane of complex numbers (today called a Riemann surface). To each value of x there correspond a finite number of values of y. Such surfaces are not easy to comprehend, and Riemann had proposed to draw curves along them in such a way that, if the surface was cut open along them, it could be opened out into a polygonal disk (see Figure 18). He was able to establish a profound connection between the minimum number of curves needed to do this for a given surface and the number of functions (becoming infinite at specified points) that the surface could then support.

Riemann surfaces

The natural problem was to see how far Riemann's ideas could be applied to the study of spaces of higher dimension. Here two lines of inquiry developed. One emphasized what could be obtained from looking at the projective geometry involved. This point of view was fruitfully applied by the Italian school of algebraic geometers. It ran into problems, which it was not wholly able to solve, having to do with the singularities a surface can possess. Whereas a locus given by $f(x, y) = 0$ may intersect itself only at isolated points, a locus given by an equation of the form $f(x, y, z) = 0$ may intersect itself along curves, a problem that caused considerable difficulties. The second approach emphasized what can be learned from the study of integrals along paths on the surface. This approach, pursued by Charles-Émile Picard and by Poincaré, provided a rich generalization of Riemann's original ideas.

On this base, conjectures were made and a general theory produced, first by Poincaré and then by the American engineer-turned-mathematician Solomon Lefschetz (1884–1972), concerning the nature of manifolds of arbitrary dimension. Roughly speaking a manifold is the n-dimensional generalization of the idea of a surface; it is a space any small piece of which looks like a piece of n-dimensional space. Such an object is often given by a single algebraic equation in $n + 1$ variables. At first their work was concerned with how these manifolds may be decomposed into pieces, counting the number of pieces and decomposing them in their turn. The result was a list of numbers, called Betti numbers in honour of the Italian mathematician Enrico Betti, who had taken the first steps of this kind to extend Riemann's work. It was only in the late 1920s that the German mathematician Emmy Noether suggested how the Betti numbers might be thought of as measuring the size of certain groups. At her

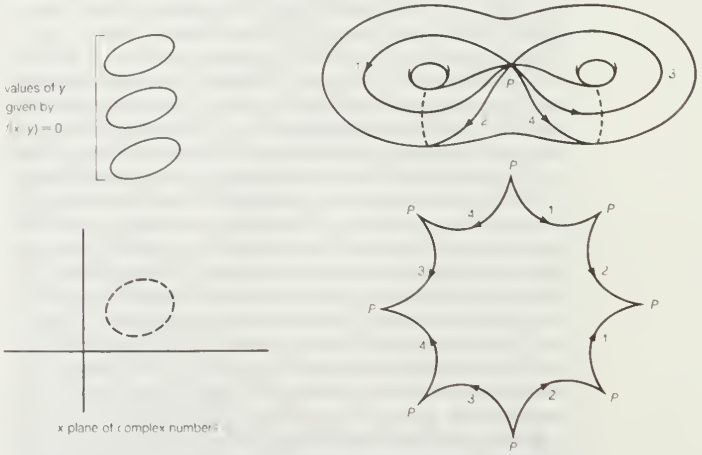

Figure 18: (Left) Pieces of a surface given by $f(x, y) = 0$; (right) if the surface is cut along the curves, an octagon is obtained

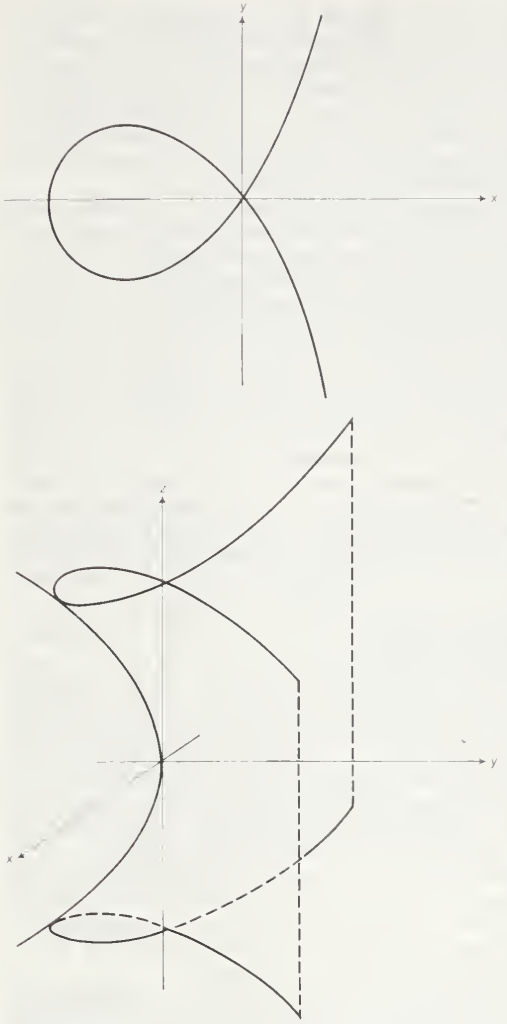

Figure 19: (Top) $f(x, y) = x^2(x + 1) - y^2 = 0$ intersects itself at $(x, y) = (0, 0)$; (bottom) $E(x, y, z) = 0 = y^2(y + z^2) - x^2$ intersects itself along the z-axis, but the origin is a triple self-intersection.

instigation a number of people then produced a theory of these groups, the so-called homology and cohomology groups of a space.

Homology and cohomology

Two objects that can be deformed into one another will have the same homology and cohomology groups. To assess how much information is lost when a space is replaced by its algebraic topological picture, Poincaré asked the crucial converse question: according to what algebraic conditions is it possible to say that a space is topologically equivalent to a sphere? He showed by an ingenious example that having the same homology is not enough and proposed a more delicate index, which has since grown into the branch of topology called homotopy theory. Being more delicate, it is both more basic and more difficult. There are usually standard methods for computing homology and cohomology groups, and they are completely known for many spaces. In contrast, there is scarcely an interesting class of spaces for which all the homotopy groups are known. And Poincaré's original question continues to resist answer, but only in the dimension in which he raised it: there is still no algebraic criterion for recognizing the 3-sphere.

Developments in pure mathematics. The interest in axiomatic systems at the turn of the century led to axiom systems for the known algebraic structures, that for the theory of fields, for example, being developed by the German mathematician Ernst Steinitz in 1910. The theory of rings (structures in which it is possible to add, subtract, and multiply but not necessarily divide) was much harder to formalize. It is important for two reasons: the theory of algebraic integers forms part of it, because algebraic integers naturally form into rings; and (as Kronecker and Hilbert had argued) algebraic geometry forms another part. The rings that arise there are rings of functions definable on the curve, surface, or manifold or are definable on specific pieces of it.

Problems in number theory and algebraic geometry are often very difficult, and it was the hope of mathematicians such as Noether, who laboured to produce a formal, axiomatic theory of rings, that by working at a more rarefied level the essence of the concrete problems would remain, while the distracting special features of any given case would fall away. This would make the formal theory both more general and easier, and to a surprising extent these mathematicians were successful.

A further twist to the development came with the work of the American mathematician Oscar Zariski (1899–1986), who had studied with the Italian school of algebraic geometers but came to feel that their method of working was imprecise. He worked out a detailed program whereby every kind of geometric configuration could be redescribed in algebraic terms. His work succeeded in producing a rigorous theory, although some, notably Lefschetz, felt that the geometry had been lost sight of in the process.

The study of algebraic geometry was amenable to the topological methods of Poincaré and Lefschetz so long as the manifolds were defined by equations whose coefficients were complex numbers. But with the creation of an abstract theory of fields it was natural to want a theory of varieties defined by equations with coefficients in an arbitrary field. This was provided for the first time by the French mathematician André Weil (b. 1906), in his *Foundations of Algebraic Geometry* (1946), in a way that drew on Zariski's work without suppressing the intuitive appeal of geometric concepts. Weil's theory of polynomial equations is the proper setting for any investigation that seeks to determine what properties of a geometric object can be derived solely by algebraic means. But it falls tantalizingly short of one topic of importance: the solution of polynomial equations in integers. This was the topic that Weil took up next.

Weil's theory of polynomial equations

The central difficulty is that in a field it is possible to divide, but in a ring it is not. The integers form a ring but not a field (dividing 1 by 2 does not yield an integer). But Weil showed that simplified versions (posed over a field) of any question about integer solutions to polynomials could be profitably asked. This transferred the questions to the domain of algebraic geometry. To count the number of solutions, Weil proposed that, since the questions were now geometric, they should be amenable to the techniques of algebraic topology. This was an audacious move, since there was no suitable theory of algebraic topology available, but Weil conjectured what results it should yield. The difficulty of Weil's conjectures may be judged by the fact that the last of them was a generalization to this setting of the famous Riemann hypothesis about the zeta function, and they rapidly became the focus of international attention.

Weil, along with Claude Chevalley, Henri Cartan, Jean Dieudonné, and others, created a group of young French mathematicians who began to publish virtually an encyclopaedia of mathematics under the name Nicolas Bourbaki, taken by Weil from an obscure general of the Franco-German War. Bourbaki became a self-selecting group of young mathematicians who were strong on algebra, and the individual Bourbaki members were interested in the Weil conjectures. In the end, they succeeded completely. A new kind of algebraic topology was developed, and the Weil conjectures were proved. The generalized Riemann hypothesis was the last to surrender, being established by the Belgian mathematician Pierre Deligne in the early 1970s. Strangely, its resolution still leaves the original Riemann hypothesis unsolved.

Bourbaki was a key figure in the rethinking of structural mathematics. Algebraic topology was axiomatized by Samuel Eilenberg, a Polish-born American mathematician and Bourbaki member, and the American mathematician Norman Steenrod. Saunders MacLane, also of the United States, and Eilenberg extended this axiomatic approach until many types of mathematical structures were presented in families, called categories. Hence there was a category consisting of all groups and all maps between

Categories

them that preserve multiplication, and there was another category of all topological spaces and all continuous maps between them. To do algebraic topology was to transfer a problem posed in one category (that of topological spaces) to another (usually that of commutative groups or rings). When he created the right algebraic topology for the Weil conjectures, the German-born French mathematician Alexandre Grothendieck, a Bourbaki of enormous energy, produced a new description of algebraic geometry. In his hands it became infused with the language of category theory. The route to algebraic geometry became steeper than ever, but the views from the summit have a naturalness and a profundity that have brought many experts to prefer it to the earlier formulations, including Weil's.

Grothendieck's formulation makes algebraic geometry the study of equations defined over rings rather than fields. Accordingly, it raises the possibility that questions about the integers can be answered directly. Building on the work of like-minded mathematicians in the United States, France, and Russia, the German Gerd Faltings triumphantly vindicated this approach when he solved the English mathematician Louis Mordell's conjecture in 1983. This conjecture states that almost all polynomial equations that define curves have at most finitely many rational solutions; the cases excluded from the conjecture are the simple ones that are much better understood.

Meanwhile, the German mathematician Gerhard Frey had pointed out that, if Fermat's last theorem is false, so that there are integers u, v, w such that $u^p + v^p = w^p$ (p greater than 5), then for these values of u, v, and p the curve $y^2 = x(x - u^p)(x + v^p)$ has properties that contradict major conjectures of the Japanese mathematicians Taniyama Yutaka and Shimura Goro about elliptic curves. Frey's observation, refined by the French mathematician Jean-Pierre Serre and proved by the American mathematician Ken Ribet, meant that by 1990 Taniyama's unproved conjectures were known to imply Fermat's last theorem.

In 1993 the English mathematician Andrew Wiles established the Shimura–Taniyama conjectures in a large range of cases that included Frey's curve and therefore Fermat's last theorem—a major feat even without the connection to Fermat. It soon became clear that the argument had a serious flaw; but in May 1995 Wiles, assisted by another English mathematician, Richard Taylor, published a different and valid approach. In so doing, Wiles not only solved the most famous outstanding conjecture in mathematics but also triumphantly vindicated the sophisticated and difficult methods of modern number theory.

Mathematical physics and the theory of groups. In the 1910s the ideas of Lie and Killing were taken up by the French mathematician Élie-Joseph Cartan, who simplified their theory and rederived the classification of what came to be called the classical complex Lie algebras. The simple Lie algebras, out of which all the others in the classification are made, were all representable as algebras of matrices, and in a sense Lie algebra is the abstract setting for matrix algebra. Connected to each Lie algebra there were a small number of Lie groups, and there was a canonical simplest one to choose in each case. The groups had an even simpler geometric interpretation than the corresponding algebras, for they turned out to describe motions that leave certain properties of figures unaltered. For example, in Euclidean three-dimensional space, rotations leave unaltered the distances between points; the set of all rotations about a fixed point turns out to form a Lie group, and it is one of the Lie groups in the classification. The theory of Lie algebras and Lie groups shows that there are only a few sensible ways to measure properties of figures in a linear space and that these methods yield groups of motions leaving the figures, which are (more or less) groups of matrices, unaltered. The result is a powerful theory that could be expected to apply to a wide range of problems in geometry and physics.

Hermann Weyl

The leader in the endeavours to make Cartan's theory, which was confined to Lie algebras, yield results for a corresponding class of Lie groups was the German-American mathematician Hermann Weyl. He produced a rich and satisfying theory for the pure mathematician and wrote extensively on differential geometry and group theory and its applications to physics. Weyl attempted to produce a theory that would unify gravitation and electromagnetism. His theory met with criticism from Einstein and was generally regarded as unsuccessful; it has been only in the last quarter of the 20th century that similar unified field theories have met with any acceptance. Nonetheless, Weyl's approach demonstrates how the theory of Lie groups can enter into physics in a substantial way.

In any physical theory the endeavour is to make sense of observations. Different observers make different observations. If they differ in choice and direction of their coordinate axes, they give different coordinates to the same points, and so on. Yet the observers agree on certain consequences of their observations: in Newtonian physics and Euclidean geometry they agree on the distance between points. Special relativity explains how observers in a state of uniform relative motion differ about lengths and times but agree on a quantity called the interval. In each case they are able to do so because the relevant theory presents them with a group of transformations that converts one observer's measurements into another's and leaves the appropriate basic quantities invariant. What Weyl proposed was a group that would permit observers in nonuniform relative motion, and whose measurements of the same moving electron would differ, to convert their measurements and thus permit the (general) relativistic study of moving electric charges.

In the 1950s the American physicists Chen Ning Yang and Robert L. Mills gave a successful treatment of the so-called strong interaction in particle physics from the Lie group point of view. Twenty years later mathematicians took up their work, and a dramatic resurgence of interest in Weyl's theory began. These new developments, which had the incidental effect of enabling mathematicians to escape the problems in Weyl's original approach, were the outcome of lines of research that had originally been conducted with little regard for physical questions. Not for the first time, mathematics was to prove surprisingly or, as the Hungarian-born American physicist Eugene Wigner said, "unreasonably effective" in science.

Cartan had investigated how much may be accomplished in differential geometry using the idea of moving frames of reference. This work, which was partly inspired by Einstein's theory of general relativity, was also a development of the ideas of Riemannian geometry that had originally so excited Einstein. In the modern theory one imagines a space (usually a manifold) made up of overlapping coordinatized pieces. On each piece, one supposes some functions to be defined, which might in applications be the values of certain physical quantities. Rules are given for interpreting these quantities where the pieces overlap. The data are thought of as a bundle of information provided at each point. For each function defined on each patch, it is supposed that at each point a vector space is available as mathematical storage space for all its possible values. Because a vector space is attached at each point, the theory is called the theory of vector bundles. Other kinds of space may be attached, thus entering the more general theory of fibre bundles. The subtle and vital point is that it is possible to create quite different bundles which nonetheless look similar in small patches. An example of this is illustrated in Figure 20. The cylinder and the Möbius band look alike in small pieces but are topologically distinct, since it is possible to give a standard sense of direction to all the lines in the cylinder but not to those in the Möbius band. Both spaces can be thought of as one-dimensional vector bundles over the circle, but they are very different. The cylinder is regarded as a "trivial" bundle, the Möbius band as a twisted one.

The theory of vector bundles

In the 1940s and '50s a vigorous branch of algebraic topology established the main features of the theory of bundles. Then, in the 1960s, work chiefly by Grothendieck and the English mathematician Michael Atiyah showed how the study of vector bundles on spaces could be regarded as the study of cohomology theory (called K theory). More significantly still, in the 1960s Atiyah, the American Isadore Singer, and others found ways of connecting this work to the study of a wide variety of questions involving partial differentiation, culminating in the celebrated

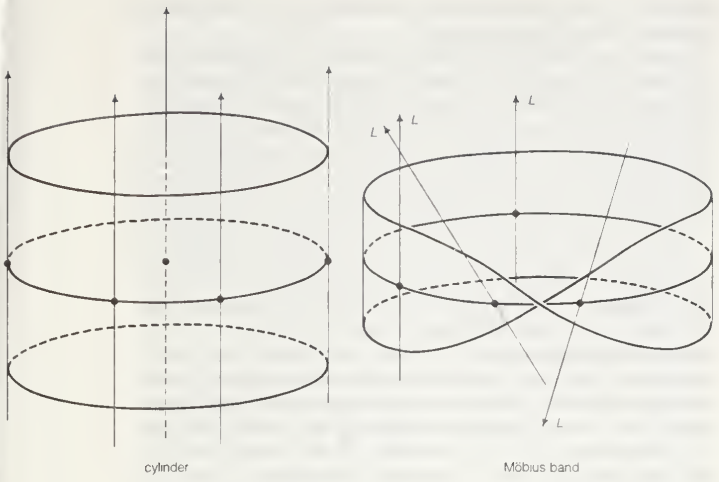

Figure 20: *Vector bundles.*
As the circle is followed clockwise around the Mcbius band, the line *L* twists through the half a turn, so the lines cannot be consistently made to point in the same direction.

Atiyah–Singer theorem for elliptic operators. (Elliptic is a technical term for the type of operator studied in potential theory.) There are remarkable implications for the study of pure geometry, and much attention has been directed to the problem of how the theory of bundles embraces the theory of Yang and Mills, which it does precisely because there are nontrivial bundles, and to the question of how it can be made to pay off in large areas of theoretical physics. These include the theories of superspace and supergravity and the string theory of fundamental particles, which involves the theory of Riemann surfaces in novel and unexpected ways. (J.J.G.)

Mathematics in China and Japan

When speaking of mathematics in East Asia, it is necessary to take into account its development in China, Korea, and Japan as a whole. Mathematicians from these countries can be considered as part of the same working community. Moreover, these scholars usually wrote with Chinese characters and thus could read one another's texts.

The common basis for the development of mathematics in East Asia was books that were written in China from the 1st through the 13th century, to which most of the subsequent works refer. For this period, the two main sources, the references found in the texts and those given in the bibliographies compiled for the dynastic annals, indicate that there are many lacunae in the books that have survived. The oldest works extant survived because they became official books.

In the 17th century few ancient Chinese mathematical works were known, and those that were known were not fully understood. Thereafter, as Chinese mathematicians became aware of European achievements, they began to look for such works throughout the country. Editions of the texts they found began to appear at the end of the 18th century and have become the main sources for the history of Chinese mathematics. Discoveries of new sources are now rare, contrary to the situation for Arabic mathematics, for example. Nevertheless, in the 20th century a mathematical book was discovered in a grave dating from the 2nd or 3rd century, which pushed back by more than three centuries what was previously known about the subject.

CHINESE MATHEMATICS TO THE 13TH CENTURY

The *Nine Chapters*

Outline of the history. The *Nine Chapters on the Mathematical Procedures* (or the *Nine Chapters*) was probably compiled in the 1st century AD. This book gathered and organized many mathematical achievements from preceding periods. It played an important part in the development of mathematics in China, for all Chinese mathematicians refer to it and most of the subjects they have worked on stem from it. Its format, which was adopted by most subsequent authors, consists of problems for which a numerical answer and a procedure for solution are given. These problems are arranged in classes that come under the heading of a general method. Many scholars wrote commentaries on the *Nine Chapters,* adding explanations and proofs, rewriting procedures, and suggesting new formulas. The most important of the commentaries to survive, attributed to Liu Hui (3rd century), contains the richest set of proofs within this tradition.

Some of the books written subsequently are known because, gathered together with the *Nine Chapters* and the astronomical treatise *Mathematical Classic of the Gnomon of Chou* and commented on in the 7th century by a group under the leadership of Li Ch'un-feng, they became the *Ten Classics of Mathematics,* the manual for officials trained in the then newly established office of mathematics. Although some people were thus officially trained as mathematicians, no major breakthrough seems to have been achieved until the 11th century.

At that time (1084) the *Ten Classics of Mathematics* was edited and printed, and this seems to have been related to renewed activity in mathematics during the 11th and 12th centuries, known today only through later quotations. This period probably paved the way for the major achievements of Chinese tradition, as they are known today only through the few books that have come down from the second half of the 13th century. China was then divided into two countries, North and South, and achievements by mathematicians of both sides are known: in the South, those of Ch'in Chiu-shao and Yang Hui (who were minor officials), and in the North, those of Li Yeh (a recluse scholar) and Chu Shih-chieh (a wandering teacher). Their contributions seem to have been arrived at independently but they attest to a common basis.

From the period after this, no valuable works survive, and there is no evidence that any important mathematical works were written. Still, some major works of the 13th century are recorded in the encyclopaedia compiled under the Yung-lo emperor (1402–24), but commentaries on these books written by the end of the 15th century show that by this time they were no longer understood.

It was only in the 16th century that the abacus appears to have come into widespread use, and most of the books of the period discuss it. But it is not possible to date the moment when it actually appeared in China.

The following discussion of the evolution of mathematical subjects within the Chinese tradition emphasizes several common characteristics of most of the achievements: a specific use of algorithms and the importance given to position, to configurations of numbers, and to parallelisms between procedures.

The Nine Chapters. This book presupposes mathematical knowledge about how to represent numbers and how to perform the four arithmetic operations. The numbers are written in Chinese characters, but, for most of the procedures described, the computations are to be performed on a surface, perhaps on the ground (see below). Most probably, as can be inferred from later accounts, the numbers were represented with counting rods, according to a decimal place-value system. Such a representation can be moved and modified within a computation. Indian and Arabic mathematicians computed (among other ways) on erasable surfaces, and it appears that arithmetic operations were performed in China in ways comparable to these, although no written computations were recorded until much later. As will be seen, setting up the computations in this way greatly influenced later mathematical developments.

Computational methods

The *Nine Chapters* contains a number of mathematical achievements, already in a mature form, that are presented by most of the subsequent books without substantial changes.

Arithmetic of fractions. Division is a central operation in the *Nine Chapters.* The numbers used throughout are of the type that results from division: "integer plus fraction." Fractions are defined to be a natural part of the result of a division, the remainder of the division being taken as the numerator and the divisor as the denominator. Thus, dividing 17 by 5, one obtains 3 as the quotient and a remainder of 2. This gives rise to the fraction $^2/_5$. The fractions are thus always less than one, and their arithmetic is

described through the use of division. To get the sum of a set of fractions, one is instructed to "multiply the numerators by the denominators that do not correspond to them, add to get the dividend. Multiply the denominators all together to get the divisor. Perform the division. If there is a remainder, name it with the divisor." The sum of a set of fractions is itself thus the result of a division, of the form integer plus fraction. All the operations are described in a similar way. The book also contains explanations of such algorithms as the "rule of three," "sharing in unequal parts," "false double position," and so on.

Formulas for the computations of areas and volumes. The *Nine Chapters* gives formulas for elementary plane and solid figures as well as for the area of the circle, segment of a circle, and sphere. All these formulas are expressed by lists of operations to perform on the data to get the result, an algorithmic expression that is common in ancient traditions (see below on the remarkable elaboration of algorithms found in the book). For example, to compute the area of the circle, the following algorithm is given: "multiply the diameter by itself, triple this, divide by four." This algorithm amounts to taking 3 for π. Commentators added improved values for π along with some derivations. Liu Hui gave two other values for π, one slightly low ($^{157}/_{50}$) and one high ($^{3927}/_{1250}$). The *Nine Chapters* also provides the correct formula for the area of the circle: "multiplying half the diameter and half the circumference, one gets the area," which Liu Hui proved.

Solution of systems of simultaneous linear equations. The chapter devoted to this topic provides a general procedure. For instance, one of its problems, on the yields from three grades of grain, leads to a system of three linear equations in three unknowns, and the procedure for the solution arranges the data on the computing surface in a table, as in Figure 21. The coefficients of the first equation are arranged in the right column. The coefficients of the second and third equations are arranged in the middle and left columns, respectively, and so on. Consequently, the numbers of the first row all correspond to the first unknown. This is an instance of a positional notation, in which the position of a number in a numerical configuration has a mathematical meaning. The main tool for the solution is the use of column reduction to obtain an equivalent configuration (see Figure 21). Next, the unknown of the third line is found by division, and hence the second and the first unknowns as well.

Positional notation

The description of the algorithm uses the structure that the configuration gives to the data on the counting surface in an essential way. Because this procedure implies a column-to-column subtraction, it gives rise to negative numbers. Detailed methods of computing with positive and negative coefficients are used to solve problems involving two to seven unknowns. This seems to be the first occurrence of negative numbers in the history of mathematics. The *Nine Chapters* also contains some knowledge that was to be reworked later.

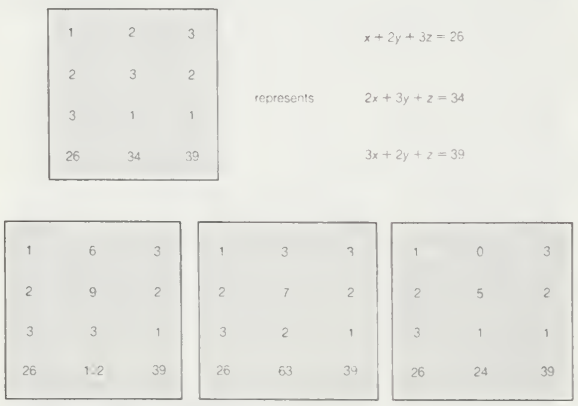

Figure 21: *The first example of a system of linear equations in the Nine Chapters.*
(Top) The coefficients of each equation are arranged in columns in the box; the coefficients of the middle column are multiplied by 3 (the first position in the right column), and the right column is then subtracted as many times as necessary to produce 0 in the first position of the middle column. (Bottom) The operation is repeated to obtain a "triangular matrix" from which the unknowns are then obtained one after the other.

Square root and cube root extraction. Algorithms in the *Nine Chapters* for finding integer parts of roots on the counting surface are based on the same idea as the arithmetic ones used today. They are described using the technical terms of division, in such a way that both roots appear to be derived from this operation. These algorithms are set up on the surface in the same way as is a division ("quotient" on the top; under it, the "dividend"; one row below, the "divisor"; at the bottom, auxiliary computations). Moreover, the two algorithms are written out, sentence by sentence, parallel to each other, so that their similarities and differences become clear.

In the writing of algorithms, there are three basic operations: iteration, conditional statements, and assignation of variables. Once the integer parts are found, the algorithms supply a fractional approximation of the root. (To find the square root of A, for example, if the integer part of the root found by the algorithm is a, the result is given as $[a + (A - a^2)/2a]$.)

In commenting on these algorithms, Liu Hui gives new approximations and suggests that one should continue computing the digits in the same way, setting 10 as denominator for the first digit, 100 as denominator for the second digit, and so on; he thus gives the root in terms of decimal fractions.

In the *Nine Chapters* a problem is solved with a quadratic equation, which appears to be conceived of as an arithmetic operation depending on square root extraction. The procedure for solving the equation is part of the procedure for root extraction. However, the equation is thought to have only one root. The theory of equations developed in China within that framework, until its apogee in the 13th century. (The solution by radicals that Babylonian mathematicians had already explored has not been found in the Chinese texts that survive.)

Problems involving right-angled triangles. The so-called Pythagorean theorem is given in the *Nine Chapters*. Formulas are provided to solve problems on right-angled triangles such as the following: "given the base, and the sum of the height and of the hypotenuse, find the height and the hypotenuse." The diameter of the inscribed circle and the side of the inscribed square are given as well.

The Commentary of Liu Hui. Liu Hui's commentary on the *Nine Chapters* is the most important text dating from before the 13th century that contains proofs. He gives proofs for the formulas of volumes that are presented in the *Nine Chapters*, and he adds new formulas for the same volumes. He also organizes these formulas, given one after the other without comment in the *Nine Chapters*, into a system in which proofs for one formula use only formulas that have been established independently. Starting from the formula of the parallelepiped, Liu Hui proves the formulas of "standard blocks," from which he then deduces other formulas. He proceeds with a small set of proof techniques, including dissection, decomposition and recomposition into known pieces, and Cavalieri's principle (which states that, if two solids of the same height are such that their corresponding sections at any level have the same areas, then they have the same volume), and so on.

Proof techniques

Liu Hui compares the algorithms given in the algebraic sections of the *Nine Chapters* with one another and demonstrates how the same formal operations, which he calls the "key-steps" of computations, are brought into play in different algorithms. Thus, in the comparison between the addition of fractions and the solution of systems of simultaneous linear equations mentioned above, Liu Hui shows that sets of numbers are involved (numerator and denominator for a fraction, the coefficients of an equation for systems of equations) which share the property that all the numbers of a set can be multiplied by the same number without altering the mathematical meaning of that set. Both algorithms proceed by multiplying the sets of numbers that enter into a problem, each by an appropriate factor, in such a way that some corresponding numbers of the sets are made equal and the other numbers multiplied to keep intact the meaning of the whole

sets. (In the case of fractions, the denominators are made equal and the numerators changed appropriately; for systems of equations, the procedure is the same as if two numbers in the same row but in different columns were made equal by an appropriate multiplication, so that one of them can be eliminated through a column-to-column subtraction; the whole columns are then multiplied by the same number so that the equations remain true). Liu Hui proceeds from these analogies to state new algorithms for the same problems.

The Ten Classics of Mathematics. The *Ten Classics of Mathematics* contains explications of the mathematical knowledge presupposed by the *Nine Chapters* (the numeration system, arithmetic operations, etc.). Most of the subjects presented rely on the algorithms presented in the *Nine Chapters:* the rule of three, sharing in unequal parts, false double position, systems of simultaneous linear equations, and so on. These algorithms are not stated in as full generality in the *Ten Classics* as they are in the *Nine Chapters,* but they are given in the solutions of particular problems. Nevertheless, it is possible to see the ongoing evolution of some of these subjects, for example, the root extraction, the solution of equations, and the summation of series. The mathematical classics by Sun Tzu and Chang Ch'iu-chien (probably written before the 5th century) employ new ways of describing the algorithms of square root and cube root extraction. The underlying procedures are the same and they are still described in parallel ways, but this parallelism shows more clearly than before the mathematical object under which both of them are actually subsumed and which is thus responsible for their similarity: namely, equation. What has changed in the description is that, just as division involves a single divisor, square root extraction is shown to have two divisors, and cube root extraction three divisors. (These divisors actually are coefficients of the equations underlying the root extractions.) The divisors are shown to play similar roles in the algorithms. Moreover, in setting up the algorithms, the divisors are arranged one above the other, yielding a positional notation for the underlying equations: the row in which a number occurs is associated with the power of the unknown whose coefficient it is.

The *Ten Classics* contains discussions of topics that are not mentioned in the *Nine Chapters* but that were to be the subject of some of the highest mathematical achievements of the Sung and Yüan dynasties (960–1368). For example, the *Mathematical Classics by Sun Tzu* presents this congruence problem: Suppose one has an unknown amount of objects. If one counts them by 3s, there remain 2 of them. If one counts them by 5s, there remain 3 of them. If one counts them by 7s, there remain 2 of them. How many objects are there? The procedure used to solve the problem is difficult to understand, however, because it is described in a very condensed manner.

Congruence problems

Some major developments from the 11th century to the 13th century. *Theory of root extraction and of equations.* In the 11th century Chia Hsien is said to have given an algorithm to find a fourth root involving a method similar to the so-called Ruffini–Horner method. In this algorithm the successive numbers that are put in each of the rows (actually the coefficients) are obtained through computations that involve only the numbers located in the rows below. Again the algorithm makes use of the configuration given to this set of numbers in an essential way. In addition, the procedures used to compute the numbers of any row are basically the same. The representation of its computation still involves a positional notation for the underlying equations. This new algorithm can be applied for square and cube root extraction as well; it is only necessary to determine the number of rows (*i.e.,* coefficients) that each of these computations involves. It was again through a reformulation of the previous root extraction procedures that a new improvement was obtained: these procedures were shown to be special cases of the same general algorithm.

The 12th-century scholar Liu I explored a method of finding roots of quadratic equations that have positive or negative coefficients; such equations arise in geometric problems. These coefficients, whatever their sign, are entered in the table of the root extraction, and the square root algorithm is adapted to each situation.

Later, in Ch'in Chiu-shao's *Mathematics in Nine Chapters* (1247), a similar algorithm is used to find "the" root of any equation. By that time, general equations were used and were represented by a positional notation (see the example in the next section), which seems to indicate that it was the slow evolution of the algorithms of root extraction and their comparison that produced the concept of equation. Similar methods (with a slightly different notation) were well known to Li Yeh, and in his *Sea-Mirror of Circle Measurements,* written only one year after Ch'in completed his book, he takes the search for the root of equations for granted. Li Yeh lived in North China, while Ch'in Chiu-shao lived in the South, and he is thought to have worked without knowing Ch'in's achievement. It is thus highly probable that these methods were well known before the middle of the 13th century.

From Chia Hsien on, another method was known for finding the root of an equation, using the coefficients of what is now called Pascal's triangle (see Figure 22) and the same positional representation.

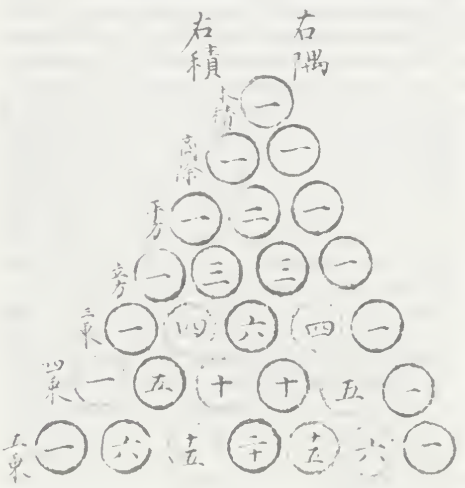

Figure 22: A Chinese representation of Pascal's triangle.

The method of the "celestial unknown." Li Yeh's book also contains a method, unknown to Ch'in Chiu-shao, which seems to have flourished in North China for some decades. This method explains how to use polynomial arithmetic to find equations to solve a problem. Li Yeh's book is the oldest surviving work that explains this method, but it was probably not the first to deal with it. In this book polynomials are also arranged according to a positional notation. Thus $x^2 - 3x + 5 + 7/x^2$ is represented as

$$\begin{matrix} 7 \\ 0 \\ 5 \\ -3 \\ 1 \end{matrix}$$

A character is added next to the 5 to indicate that it is a constant term. The location of the coefficient indicates the power of the indeterminate with which it is associated. This indeterminate is called the celestial unknown.

It is known that some mathematicians used this representation for polynomials in two or three unknowns. In his book *The Jade Mirror of the Four Unknowns,* Chu Shih-chieh makes use of four unknowns. Starting from the centre, in the two horizontal and the two vertical directions, he puts in increasing order of their powers what comes from each of the four unknowns. In such problems, where there is more than one unknown, he has to use a method of elimination of a common unknown to two equations.

Polynomials in several unknowns

Indeterminate analysis. Ch'in Chiu-shao's book also contains algorithms for the general congruence problem, some examples of which are given in Sun Tzu's treatise, where its solution was too obscure to be understood. This

problem amounts to determining a number, the remainders of which are known when it is divided by given numbers (called moduli). There is no extant work between Sun's treatise and Ch'in's book of 1247 that reveals how this algorithm was elaborated. Such problems seem to have been worked out because of calendrical computation. Ch'in Chiu-shao introduces his discussion of these problems by saying that his goal is to clarify several procedures used by astronomers who were applying them without understanding them. His solution is known today as the Chinese remainder theorem. He deals with the case when moduli are relatively prime, and then reduces the case when they are not to it. The first case is easily solved when x can be found that satisfies the congruence $xa \equiv 1 \pmod{b}$, a and b being two given relatively prime numbers (suppose $a < b$). Ch'in gives an algorithm for this, using a sequence of quotients in searching for the greatest common divisor of a and b, which is also the sequence of convergents for the continued fraction for b/a. Having them, he is then able to compute x.

In addition, the summation of series was developed to a greater extent during this period.

The decline of the Sung-Yüan mathematics. Little is known about what happened after Chu Shih-chieh. In the 16th century a mathematician commenting on Li Yeh's *Sea-Mirror of Circle Measurements* no longer understood the method of the celestial unknown. By the 17th century it seems to have been completely forgotten. Rods were then no longer used as a counting tool, so perhaps Chinese algebraic positional notations, deprived of the instrument on which they were based, could not be understood. On the other hand, there was a rapid diffusion of the abacus, for which many books were written, including the *Systematic Treatise on Arithmetic* by Ch'eng Ta-wei (1592). This book explains in detail arithmetic on the abacus. Editions of this work remained popular until the 20th century.

When the Jesuits arrived in China at the end of the 16th century, they found people interested in science (so that they were accepted in China because of their scientific knowledge) but unaware of the Chinese past in mathematics. An era of translations of Western works started then (the six first books of Euclid's *Elements* were translated by a Jesuit and a Chinese in 1607), followed by a period when Chinese mathematicians attempted to find ancient books, to understand them, and to make a synthesis of the Chinese and Western traditions. In the 18th century, with the help of Western algebra, Mei Chüeh-ch'eng could understand again the ancient texts dealing with the method of the celestial unknown.

JAPAN IN THE 17TH CENTURY

The introduction of Chinese books. Very little is known of the history of Japanese mathematics before the 17th century. Through contacts with Chinese civilization, first mediated through Korea and then directly, there was, beginning in the seventh century, a flow of Chinese science to Japan. For example, the *Ten Classics of Mathematics* was introduced, along with the counting rods. Yet no Japanese book before the end of the 16th century is known to deal with mathematics. At that time another phase of importation began: the abacus and the *Systematic Treatise on Arithmetic* became known in Japan, where, however, they did not supplant the use of rods. Moreover, many books were taken from Korea to Japan, and perhaps in that way two Chinese books, the *Mathematical Treatise by Yang Hui* and the *Introduction to the Study of Mathematics* (written by Chu Shih-chieh in 1299), arrived in Japan. In those books, Japanese scholars could find the solution for systems of simultaneous linear equations, the search for the root of an equation according to the methods used in China in the 13th century, and applications of the method of the celestial unknown, although these were not easily understandable. Books about calendrical computations, containing mathematical knowledge, were also imported. Chinese mathematics greatly influenced the development of Japanese mathematics (for example, its algebraic orientation) and defined the context in which Japanese tradition opened to European mathematics.

Influence of Chinese texts

Later, at the beginning of the Tokugawa period (1603–1867), contacts with foreigners were limited to the trade with Chinese and Dutch boats through the harbour of Nagasaki. Some Chinese books, which may have contained Western knowledge, as well as Dutch books entered Japan secretly, but it is difficult to state how much, or what kind of, mathematical knowledge went through that channel.

The elaboration of Chinese methods. Although not the first mathematical book written in Japan, *Jingoki*, published in 1627 by Mitsuyoshi Yoshida, seems to be the first book that played an important part in the Japanese tradition. Inspired by the *Systematic Treatise on Arithmetic*, it described in Japanese the use of the soroban, an improvement of the Chinese abacus, and introduced some Chinese knowledge. Its many editions contributed to popularizing mathematics; most of the works on mathematics in Japan were written in Chinese and could not be widely read. In its enlarged edition of 1641, *Jingoki* introduced the method of performing computations with counting rods, which were no longer used in China. Moreover, Yoshida added "difficult problems" (*idai*), inspired by its Chinese source and left without solutions, which he recommended be posed to mathematicians. This initiated a tradition of challenges, reminiscent of those that took place in Europe during the Renaissance, that stimulated strongly the development of mathematics. In this context, in the 1650s, mathematicians, relying on counting-rod computations and looking for new methods of solution, began to understand by themselves the methods of Chinese algebra, as they were hinted at in the *Introduction to the Study of Mathematics*, which was reprinted in Japan in 1658.

These methods became a systematic tool for the solutions of any problem—what settled the algebraic framework for a mathematical development where equations and problems are essentially linked—and many books were published that introduced mathematicians to the method of finding the roots of equations or to the use of polynomial algebra to set down equations in order to solve problems. One of them, the *Kokon sanpoki* (1671), by Kazuyuki Sawaguchi, pointed out that "erroneous" problems could have more than one solution (equations could have more than one root) and left unanswered difficult problems involving simultaneous equations of the nth degree. The equations for their solutions were published in 1674 by Seki Kōwa (Takakazu), who was later referred to as the founder of the Japanese tradition of mathematics, called Wasan, that was based on Chinese mathematics. Seki founded a school of mathematics that became the most important one in Japan. As in the other schools, disciples had to keep the school methods secret, and only the best among them knew most of these methods. Only slowly did they publish their secrets, which hindered the free circulation of ideas (at this time, mathematics was widely practiced in Japan as a leisure activity) and which makes any attribution very difficult.

Wasan

Explanations about how to use Seki's equations to derive Sawaguchi's problems were published in 1685 by one of his disciples, Takebe Katahiro. Seki had designed for this purpose a "literal" written algebra using characters, thus liberating mathematicians from counting rods; he kept for equations the positional notation with respect to one unknown, the coefficients being expressed in terms of other unknowns. In establishing equations among several unknowns for the solution of a problem, he had to introduce procedures equivalent to computations of determinants in order to eliminate unknowns between simultaneous equations. Further research elaborated these procedures.

Seki devised a classification of problems that amounted to a classification of equations, which took into consideration negative roots and multiple roots, noticed by Sawaguchi; for this purpose he adapted the Chinese algorithms from the 13th century. Seki and his disciples thus improved upon Chinese methods in many ways, opening new directions for the development of mathematics in Japan (for example, in their work on infinite series, the subject of research by contemporary European scientists as well).

Matter: Its Properties, States, Varieties, and Behaviour

The tangible universe—that is, everything that has mass and occupies space—is made of matter. Because it is difficult to identify anything that is not matter, it is more meaningful to consider the specific characteristics of matter than to attempt to provide a rigorous definition.

This article deals with those important forms of matter typically encountered—such as solids, liquids, and gases—for which the basic building blocks are atoms. (Other types of matter do exist, such as the ultradense nuclear matter of neutron stars and the isolated subatomic particles in interstellar space.) There are more than 100 distinctly different types of atoms, corresponding to the different chemical elements. Each atom consists of negatively charged point-like electrons swarming around a small positively charged nucleus made up of protons and neutrons. The number of electrons ranges from 1 (for hydrogen) to 92 (for uranium, the heaviest known naturally occurring element) to 110 (for the heaviest element thus far known). The diameter of a typical atom, corresponding to the size of the electron swarm, is about 100 million times smaller than one inch. The nucleus within the atom is considerably smaller; it has a diameter that is roughly 100,000 times smaller than the atomic diameter. The electron is believed to be an undividable elementary building block of matter. The protons and neutrons that make up the nucleus are themselves made up of more elementary building blocks (called quarks). This internal structure of the nucleus does not enter into the properties of solids, liquids, and gases, however. It is the interactions between the electron swarms that are responsible for binding atoms together into small chemically bonded groups of atoms called molecules and into the large groups of bonded atoms that constitute solids. In solids the atoms are in intimate contact, and chemical bonds keep them locked into a rigid structure; in liquids they are close together but have the freedom to maneuver around each other; and in gases they are far apart (relative to their size).

This article describes the properties of the different phases of matter: solid, liquid, and gas. A given material can exist, depending on the conditions, in different phases, and so changes from one phase to another are discussed. Within the solid state, there are important distinctions (especially in the way that the atoms are arranged) between crystalline solids, quasicrystals, and amorphous solids. Liquid crystals are complex anisotropic liquids that exhibit unique properties, as do plasmas, which are electrically conducting collections of ionized particles. In the plasma state (found in the Sun, for example) high temperatures cause electrons and nuclei to separate and exhibit pronounced electrical behaviour. Another form of matter consists of atomic or molecular clusters that are too small to act as bulk solids and yet behave quite differently from individual atoms or molecules. The interesting properties of materials at low temperature and at high pressure are described as well. For additional information about the basic constituents and structure of matter, see the articles SUBATOMIC PARTICLES, ATOMS, and CHEMICAL ELEMENTS. (R.Z.)

For coverage of related topics in the *Macropædia* and *Micropædia*, see the *Propædia*, sections 124 and 125, and the *Index*.

This article is divided into the following sections:

PHASE CHANGES

GENERAL CONSIDERATIONS

A system is a portion of the universe that has been chosen for studying the changes that take place within it in response to varying conditions. A system may be complex, such as a planet, or relatively simple, as the liquid within a glass. Those portions of a system that are physically distinct and mechanically separable from other portions of the system are called phases. When a phase in one form is altered to another form, a phase change is said to have occurred.

Phases within a system exist in a gaseous, liquid, or solid state. Solids are characterized by strong atomic bonding and high viscosity, resulting in a rigid shape. Most solids are crystalline, inasmuch as they have a three-dimensional periodic atomic arrangement; some solids (such as glass) lack this periodic arrangement and are noncrystalline, or amorphous. Gases consist of weakly bonded atoms with no long-range periodicity; gases expand to fill any available space. Liquids have properties intermediate between those of solids and gases. The molecules of a liquid are condensed like those of a solid. Liquids have a definite volume, but their low viscosity enables them to change shape as a function of time. The matter within a system may consist of more than one solid or liquid phase, but a system can contain only a single gas phase, which must be of homogeneous composition because the molecules of gases mix completely in all proportions.

SYSTEM VARIABLES

Systems respond to changes in pressure, temperature, and chemical composition, and, as this happens, phases may be created, eliminated, or altered in composition. For example, an increase in pressure may cause a low-density liquid to convert to a denser solid, while an increase in temperature may cause a solid to melt. A change of composition might result in the compositional modification of a preexisting phase or in the gain or loss of a phase.

The phase rule

The classification and limitations of phase changes are described by the phase rule, as proposed by the American chemist J. Willard Gibbs in 1876 and based on a rigorous thermodynamic relationship. The phase rule is commonly given in the form $P + F = C + 2$. The term P refers to the number of phases that are present within the system, and C is the minimum number of independent chemical components that are necessary to describe the composition of all phases within the system. The term F, called the variance, or degrees of freedom, describes the minimum number of variables that must be fixed in order to define a particular condition of the system.

Phase relations are commonly described graphically in terms of phase diagrams (see Figure 1). Each point within the diagram indicates a particular combination of pressure and temperature, as well as the phase or phases that exist stably at this pressure and temperature. All phases in Figure 1 have the same composition—that of silicon dioxide, SiO_2. The diagram is a representation of a one-component (unary) system, in contrast to a two-component (binary), three-component (ternary), or four-component (quaternary) system. The phases coesite, low quartz, high quartz, tridymite, and cristobalite are solid phases composed of silicon dioxide; each has its own atomic arrangement and distinctive set of physical and chemical properties. The most common form of quartz (found in beach sands and granites) is low quartz. The region labeled anhydrous melt consists of silicon dioxide liquid.

The unary system SiO_2

Different portions of the silicon dioxide system may be examined in terms of the phase rule. At point A a single solid phase exists—low quartz. Substituting the appropriate values into the phase rule $P + F = C + 2$ yields $1 + F = 1 + 2$, so $F = 2$. For point A (or any point in which only a single phase is stable) the system is divariant—*i.e.*, two degrees of freedom exist. Thus, the two variables (pressure and temperature) can be changed independently, and the same phase assemblage continues to exist.

Point B is located on the boundary curve between the stability fields of low quartz and high quartz. At all points along this curve, these two phases coexist. Substituting values in the phase rule ($2 + F = 1 + 2$) will cause a variance of 1 to be obtained. This indicates that one independent variable can be changed such that the same pair of phases will be retained. A second variable must be changed to conform to the first in order for the phase assemblage to remain on the boundary between low and high quartz. The same result holds for the other boundary curves in this system.

Point C is located at a triple point, a condition in which three stability fields intersect. The phase rule ($3 + F = 1 + 2$) indicates that the variance is 0. Point C is therefore an invariant point; a change in either pressure or temperature results in the loss of one or more phases. The phase rule also reveals that no more than three phases can stably coexist in a one-component system because additional phases would lead to negative variance.

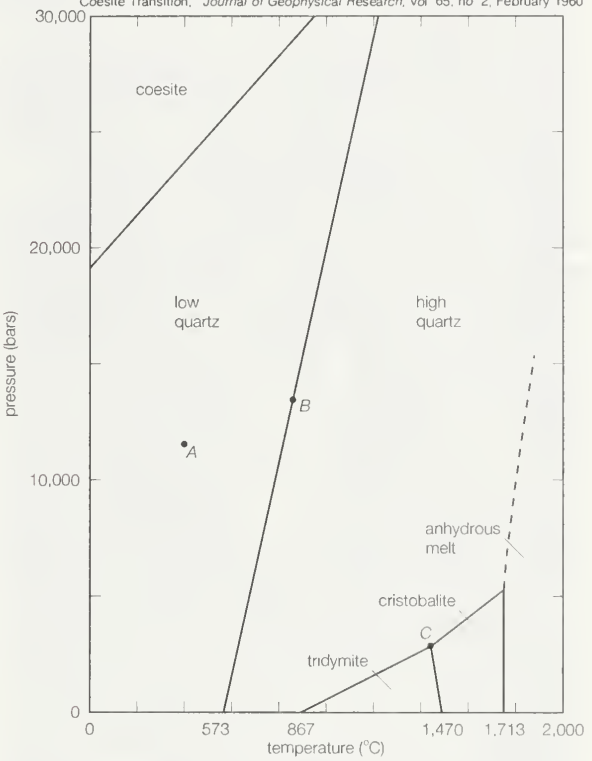

Figure 1: Phase diagram for the unary system SiO_2.

The binary sphene-anorthite system

Consider the binary system (Figure 2) that describes the freezing and melting of the minerals sphene ($CaSiTiO_5$), or titanite, and anorthite feldspar ($CaAl_2Si_2O_8$). The melt can range in composition from pure $CaSiTiO_5$ to pure $CaAl_2Si_2O_8$, but the solids show no compositional substitution. All phases therefore have the composition of $CaSiTiO_5$, $CaAl_2Si_2O_8$, or a liquid mixture of the two. The system in the figure has been examined at atmospheric pressure; because the pressure variable is fixed, the phase rule is expressed as $P + F = C + 1$. In this form it is called the condensed phase rule, for any gas phase is either condensed to a liquid or is present in negligible amounts. The phase diagram shows a vertical temperature coordinate and a horizontal compositional coordinate (ranging from pure $CaSiTiO_5$ at the left to pure $CaAl_2Si_2O_8$ at the right).

The phase fields (separated by the solid curves) contain either one or two phases. Any point in a one-phase field corresponds to a single phase whose composition is indicated directly below on the horizontal axis. For example, point A presents a liquid whose composition is 70 percent $CaAl_2Si_2O_8$ and 30 percent $CaSiTiO_5$. The compositions of phases in a two-phase field are determined by construction

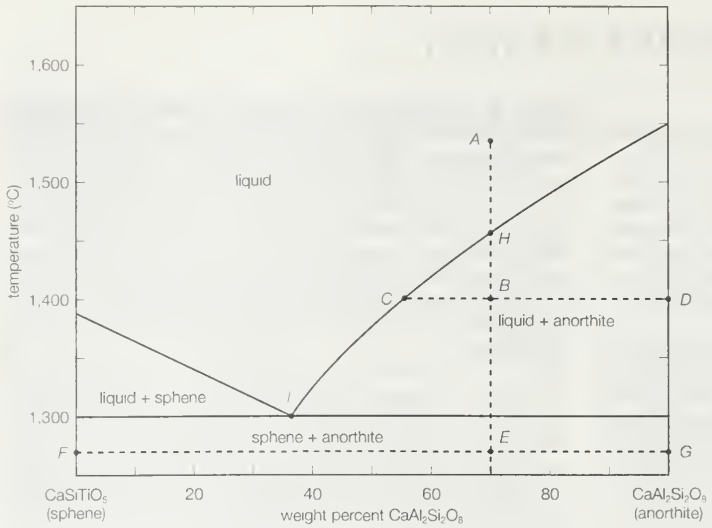

Figure 2: Phase diagram for the binary system $CaSiTiO_5$-$CaAl_2Si_2O_8$.

From E G. Ehlers, *The Interpretation of Geological Phase Diagrams*, © 1987 Dover Publications, Inc., after A T Prince, "The System Albite-Anorthite-Sphene," *The Journal of Geology*, vol 51, no 1, 1943, © The University of Chicago Press, publisher

of a horizontal (constant-temperature) line from the point of interest to the extremities of the two-phase field. Thus, a sample with composition *B* consists of liquid *C* (43 percent $CaSiTiO_5$ and 57 percent $CaAl_2Si_2O_8$) and solid anorthite *D*. A sample at point *E* at a lower temperature consists of the solids sphene (*F*) and anorthite (*G*).

Freezing-point depression

Liquid $CaAl_2Si_2O_8$ cools to produce solid anorthite at 1,550° C, whereas liquid $CaSiTiO_5$ cools to produce solid sphene at 1,390° C. If the batch were a mixture of the two components, the freezing temperature of each of these minerals would be depressed. In a melt consisting of a single component, such as $CaSiTiO_5$, all atoms could add to sphene nuclei to form crystals of sphene. If, however, the melt contained 30 percent $CaAl_2Si_2O_8$, the rate of formation of sphene nuclei would be decreased, as 30 percent of the melt could not contribute to their formation. In order to increase the rate of formation of sphene nuclei and promote crystallization, the temperature of the melt must be decreased below the freezing point of pure $CaSiTiO_5$. When cooled, liquid *A* does not begin crystallization until temperature *II* is reached. Pure anorthite crystals precipitate from the melt. Depletion of $CaAl_2Si_2O_8$ from the melt causes the melt composition to become relatively enriched in $CaSiTiO_5$, with consequent additional depression of the anorthite freezing point. As freezing continues, the liquid composition changes until the minimum point is reached at *I*. This point is called the eutectic. It is the lowest temperature at which a liquid can exist in this system. At the eutectic, both anorthite and sphene crystallize together at a fixed temperature and in a fixed ratio until the remaining liquid is consumed. All intermediate liquid compositions migrate during crystallization to the eutectic. The melting sequence of sphene-anorthite mixtures is exactly the opposite of the freezing sequence (*i.e.*, melting of any anorthite-sphene mixture begins at the eutectic).

Depression of the freezing point of a compound by the addition of a second component is common in both binary and more complex systems. This usually occurs when the solid phases either have a fixed composition or show limited solid solution. Common examples are the mixing of ice and salt (NaCl) or the use of ethylene glycol (antifreeze) to depress the freezing point of water (see Figure 3).

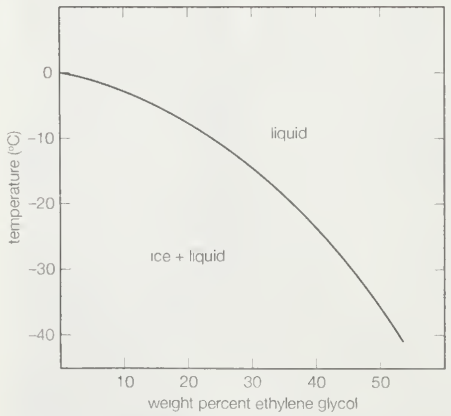

Figure 3: The depression of the freezing point of water as a function of the addition of ethylene glycol.

APPLICATIONS TO PETROLOGY

Systematic investigation of the phase changes of the more common anhydrous mineral groups was initiated by the Canadian-born American petrologist Norman L. Bowen and his coworkers at the Geophysical Laboratory of the Carnegie Institution of Washington, D.C., in the early 20th century. This work was generally limited to systems at atmospheric pressure. Subsequent advances in technology have permitted the examination of rock systems in the presence of water pressure and ultrahigh confining pressures. Materials can now be systematically examined under conditions that range from those at the Earth's surface to those simulating conditions that exist at the core. This has led to a vast increase in knowledge about the conditions of formation of both igneous and metamorphic rocks. Synthetic equivalents of almost every mineral or rock system can now be produced in the laboratory. Even gemstones such as diamonds are routinely synthesized.

Rock formation

Typical of the data now available are the freezing-melting curves (Figure 4) of the common volcanic rock basalt (and its coarse-grained equivalent, gabbro). Figure 4A shows the crystallization range (shaded) for basaltic melts as a function of lithostatic pressure; this pressure is due to depth of burial. The two short lines show the approximate position of a transition region between gabbro and its denser solid equivalent, eclogite (a sodium-pyroxene + garnet rock). The melting curves have a positive slope, as the solids are denser than their equivalent melts and are thus favoured (enlarged) with increasing pressure.

In the presence of water pressure (P_{H_2O}), the freezing-melting curves are depressed (Figure 4B) because the water acts as another component. The slope of the curves is also influenced by the presence of a hydrous solid phase, hornblende, whose approximate stability field is indicated by the dashed line. The changes in liquid composition and crystallization sequences have been determined. Similar information is available for most common igneous rocks.

In 1915 the Finnish petrologist Pentii E. Eskola set up a classification scheme for metamorphic rocks that was based on metamorphic facies. Each facies was defined by the presence of one or more common mineral assemblages.

The stability limits of these assemblages subsequently have been determined by laboratory studies. As a result, placing a metamorphic rock within a particular facies indicates the broad pressure-temperature region in which the rock formed. (See MINERALS AND ROCKS: *Metamorphic rocks: Metamorphic facies* for the pressure-temperature regions of the major metamorphic facies.) For example, a rock containing sodium-rich pyroxene and garnet is placed within the eclogite facies, which indicates that it formed at pressures greater than about 12 kilobars and temperatures above approximately 600° C. Rocks in the blueschist facies contain the blue amphibole glaucophane; such rocks are stable at high pressures and relatively low temperatures.

A large variety of schemes are available to provide more detailed information on the temperatures and pressures of formation of both igneous and metamorphic rocks. These may use phase relations, stable isotopes, or the compositions of coexisting mineral pairs. (E.G.E.)

SOLID STATE

Crystalline solids

CLASSIFICATION

The definition of a solid appears obvious; a solid is generally thought of as being hard and firm. Upon inspection, however, the definition becomes less straightforward. A cube of butter, for example, is hard after being stored in a refrigerator and is clearly a solid. After remaining on the kitchen counter for a day, the same cube becomes quite soft, and it is unclear if the butter should still be considered a solid. Many crystals behave like butter in that they are hard at low temperatures but soft at higher temperatures. They are called solids at all temperatures below their melting point. A possible definition of a solid is an object that retains its shape if left undisturbed. The pertinent issue is how long the object keeps its shape. A highly viscous fluid retains its shape for an hour but not a year. A solid must keep its shape longer than that.

The basic units of solids are either atoms or atoms that have combined into molecules. The electrons of an atom move in orbits that form a shell structure around the nucleus. The shells are filled in a systematic order, with each shell accommodating only a small number of electrons. Different atoms have different numbers of electrons, which are distributed in a characteristic electronic structure of filled and partially filled shells. The arrangement of an atom's electrons determines its chemical properties. The properties of solids are usually predictable from the properties of their constituent atoms and molecules, and the different shell structures of atoms are therefore responsible for the diversity of solids.

All occupied shells of the argon (Ar) atom, for example, are filled, resulting in a spherical atomic shape. In solid argon the atoms are arranged according to the closest packing of these spheres. The iron (Fe) atom, in contrast, has one electron shell that is only partially filled, giving the atom a net magnetic moment. Thus, crystalline iron is a magnet. The covalent bond between two carbon (C) atoms is the strongest bond found in nature. This strong bond is responsible for making diamond the hardest solid.

The two short lines indicate the approximate position of a transition between gabbro and its denser equivalent, eclogite. (B) The crystallization range (shaded) of gabbroic bulk composition as a function of water pressure. The abbreviation "hb" denotes hornblende.

Long-range order

A solid is crystalline if it has long-range order. Once the positions of an atom and its neighbours are known at one point, the place of each atom is known precisely throughout the crystal. Most liquids lack long-range order, although many have short-range order. Short range is defined as the first- or second-nearest neighbours of an atom. In many liquids the first-neighbour atoms are arranged in the same structure as in the corresponding solid phase. At distances that are many atoms away, however, the positions of the atoms become uncorrelated. These fluids, such as water, have short-range order but lack long-range order. Certain liquids may have short-range order in one direction and long-range order in another direction; these special substances are called liquid crystals. Solid crystals have both short-range order and long-range order.

Solids that have short-range order but lack long-range order are called amorphous. Almost any material can be made amorphous by rapid solidification from the melt (molten state). This condition is unstable, and the solid will crystallize in time. If the timescale for crystallization is years, then the amorphous state appears stable. Glasses are an example of amorphous solids; they are discussed below in the section *Amorphous solids*. In crystalline silicon (Si) each atom is tetrahedrally bonded to four neighbours. In amorphous silicon (a-Si) the same short-range order exists, but the bond directions become changed at distances farther away from any atom. Amorphous silicon is a type of glass. Quasicrystals are another type of solid that lack long-range order (see below *Quasicrystals*).

Most solid materials found in nature exist in polycrystalline form rather than as a single crystal. They are actually composed of millions of grains (small crystals) packed together to fill all space. Each individual grain has a different orientation than its neighbours. Although long-range order exists within one grain, at the boundary between grains, the ordering changes direction. A typical piece of iron or copper (Cu) is polycrystalline. Single crystals of metals are soft and malleable, while polycrystalline metals are harder and stronger and are more useful industrially. Most polycrystalline materials can be made into large single crystals after extended heat treatment. In the past blacksmiths would heat a piece of metal to make it malleable; heat makes a few grains grow large by incorporating smaller ones. The smiths would bend the softened metal into shape and then pound it awhile; the pounding would make it polycrystalline again, increasing its strength.

Categories of crystals

Crystals are classified in general categories, such as insulators, metals, semiconductors, and molecular solids. A single crystal of an insulator is usually transparent and resembles a piece of glass. Metals are shiny unless they have rusted. Semiconductors are sometimes shiny and sometimes transparent but are never rusty. Many crystals can be classified as a single type of solid, while others have intermediate behaviour. Cadmium sulfide (CdS) can be prepared in pure form and is an excellent insulator; when impurities are added to cadmium sulfide, it becomes an interesting semiconductor. Bismuth (Bi) appears to be a metal, but the number of electrons available for electrical conduction is similar to that of semiconductors. In fact, bismuth is called a semimetal. Molecular solids are usually crystals formed from molecules or polymers. They can be insulating, semiconducting, or metallic, depending on the type of molecules in the crystal. New molecules are continuously being synthesized, and many are made into crystals. The number of different crystals is enormous.

STRUCTURE

Crystals can be grown under moderate conditions from all 92 naturally occurring elements except helium, and helium can be crystallized at low temperatures by using 25 atmospheres of pressure. Binary crystals are composed of two elements. There are thousands of binary crystals; some examples are sodium chloride (NaCl), alumina (Al_2O_3), and ice (H_2O). Crystals can also be formed with three or more elements.

A basic concept in crystal structures is the unit cell. It is the smallest unit of volume that permits identical cells to be stacked together to fill all space. By repeating the pattern of the unit cell over and over in all directions, the entire crystal lattice can be constructed. A cube is the simplest example of a unit cell. Two other examples are shown in Figure 5. The first is the unit cell for a face-centred cubic lattice, and the second is for a body-centred cubic lattice. These structures are explained in the following paragraphs. There are only a few different unit-cell shapes, so many different crystals share a single unit-cell type. An important characteristic of a unit cell is the number of atoms it contains. The total number of atoms in the entire crystal is the number in each cell multiplied by the number of unit cells. Copper and aluminum (Al) each have one atom per unit cell, while zinc (Zn) and sodium chloride have two. Most crystals have only a few atoms per unit cell, but there are some exceptions. Crystals of polymers, for example, have thousands of atoms in each unit cell.

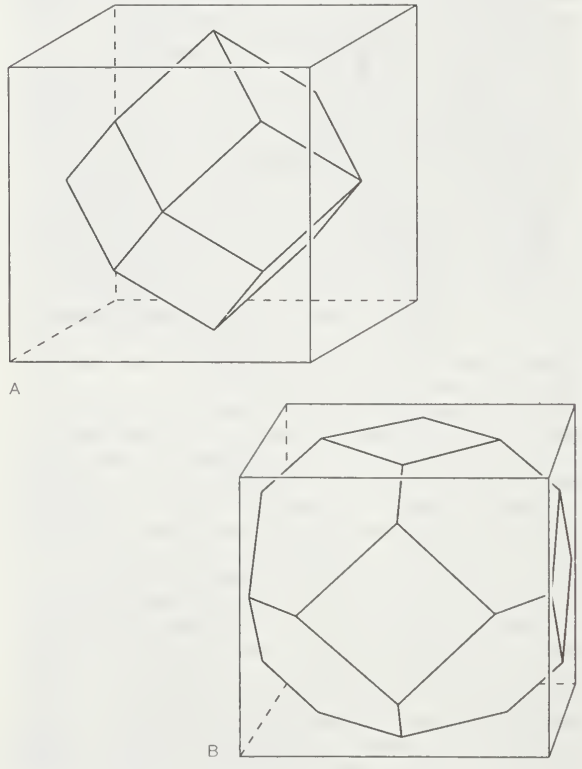

Figure 5: Unit cells for (A) face-centred and (B) body-centred cubic lattices.

Arrangements of atoms in crystals

The elements are found in a variety of crystal packing arrangements. The most common lattice structures for metals are those obtained by stacking the atomic spheres into the most compact arrangement. There are two such possible periodic arrangements. In each, the first layer has the atoms packed into a plane-triangular lattice in which every atom has six immediate neighbours. Figure 6 shows this arrangement for the atoms labeled *A*. The second layer is shaded in the figure. It has the same plane-triangular structure; the atoms sit in the holes formed by the first layer. The first layer has two equivalent sets of holes, but the atoms of the second layer can occupy only one set. The third layer, labeled *C*, has the same structure, but there are two choices for selecting the holes that the atoms will occupy. The third layer can be placed over the atoms of the first layer, generating an alternate layer sequence *ABABAB* . . . , which is called the hexagonal-closest-packed (hcp) structure. Cadmium and zinc crystallize with this structure. The second possibility is to place the atoms of the third layer over those of neither of the first two but instead over the set of holes in the first layer that remains unoccupied. The fourth layer is placed over the first, and so there is a three-layer repetition *ABCABCABC* . . . , which is called the face-centred cubic (fcc), or cubic-closest-packed, lattice. Copper, silver (Ag), and gold (Au) crystallize in fcc lattices. In the hcp and the fcc structures the spheres fill 74 percent of the volume, which represents the closest possible packing of spheres. Each atom has 12 neighbours. The number of atoms in a unit cell is two for hcp structures and one for fcc. There are 32 metals that have the hcp lattice and 26 with the fcc. Another possible arrangement is the body-centred cubic (bcc) lattice, in which each atom has eight neighbours arranged at the corners of a cube. Figure 7A shows the cesium chloride (CsCl) structure, which is a cubic arrangement. If all atoms in this structure are of the same species, it is a bcc lattice. The spheres occupy 68 percent of the volume. There are 23 metals with the bcc arrangement. The sum of these three numbers (32 + 26 + 23) exceeds the number of elements that form metals (63), since some elements are found in two or three of these structures.

The fcc structure is also found for crystals of the rare gas solids neon (Ne), argon (Ar), krypton (Kr), and xenon (Xe). Their melting temperatures at atmospheric pressure are: Ne, 24.6 K; Ar, 83.8 K; Kr, 115.8 K; and Xe, 161.4 K.

Structures of carbon

The elements in the fourth row of the periodic table—carbon, silicon, germanium (Ge), and α-tin (α-Sn)—prefer covalent bonding. Carbon has several possible crystal structures. Each atom in the covalent bond has four first-neighbours, which are at the corners of a tetrahedron. This arrangement is called the diamond lattice and is shown in Figure 7C. There are two atoms in a unit cell, which is fcc. Large crystals of diamond are valuable gemstones. The crystal has other interesting properties; it has the highest sound velocity of any solid and is the best conductor of heat. Besides diamond, the other common form of carbon is graphite, which is a layered material. Each carbon atom has three coplanar near neighbours, forming an arrangement called the honeycomb lattice. Three-dimensional graphite crystals are obtained by stacking similar layers.

Another form of crystalline carbon is based on a molecule with 60 carbon atoms called buckminsterfullerene (C_{60}). The molecular shape is spherical. Each carbon is bonded to three neighbours, as in graphite, and the spherical shape is achieved by a mixture of 12 rings with five sides and 20 rings with six sides. Similar structures were first visualized by the American architect R. Buckminster Fuller for geodesic domes. The C_{60} molecules, also called buckyballs, are quite strong and almost incompressible. Crystals are formed such that the balls are arranged in an fcc lattice with a one-nanometre spacing between the centres of adjacent balls. The similar C_{70} molecule has the shape of a rugby ball; C_{70} molecules also form an fcc crystal when stacked together. The solid fullerenes form

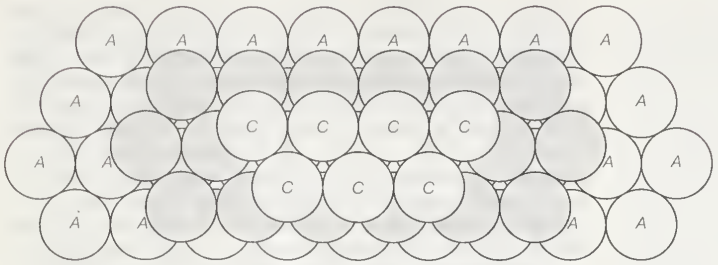

Figure 6: *Stacking of spheres in closest-packed arrangements.* The atoms of the second layer (shaded) sit in the holes formed by the atoms of the first layer (labeled *A*). If the atoms of the third layer are placed in positions labeled *C* and the structure is repeated (*ABCABC . . .*), the face-centred cubic lattice is formed. If the third layer is placed directly over the atoms of the first layer (*A*) and the structure is repeated (*ABABAB . . .*), the hexagonal closest-packed arrangement is obtained.

molecular crystals, with weak binding—provided by van der Waals interactions—between the molecules.

Many elements form diatomic gases: hydrogen (H), oxygen (O), nitrogen (N), fluorine (F), chlorine (Cl), bromine (Br), and iodine (I). When cooled to low temperature, they form solids of diatomic molecules. Nitrogen has the hcp structure, while oxygen has a more complex structure.

The most interesting crystal structures are those of elements that are neither metallic, covalent, nor diatomic. Although boron (B) and sulfur (S) have several different crystal structures, each has one arrangement in which it is usually found. Twelve boron atoms form a molecule in the shape of an icosahedron (Figure 8). Crystals are formed by stacking the molecules. The β-rhombohedral structure of boron has seven of these icosahedral molecules in each unit cell, giving a total of 84 atoms. Molecules of sulfur are usually arranged in rings; the most common ring has eight atoms. The typical structure is α-sulfur, which has 16 molecules per unit cell, or 128 atoms. In the common crystals of selenium (Se) and tellurium (Te), the atoms are arranged in helical chains, which stack like cordwood. However, selenium also makes eight-atom rings, similar to sulfur, and forms crystals from them. Sulfur also makes helical chains, similar to selenium, and stacks them together into crystals.

Binary crystal structures

Binary crystals are found in many structures. Some pairs of elements form more than one structure. At room temperature, cadmium sulfide may crystallize either in the zinc blende or wurtzite structure. Alumina also has two possible structures at room temperature, α-alumina (corundum) and β-alumina. Other binary crystals exhibit different structures at different temperatures. Among the most complex crystals are those of silicon dioxide (SiO_2), which has seven different structures at various temperatures and pressures; the most common of these structures is quartz. Some pairs of elements form several different crystals in which the ions have different chemical valences. Cadmium (Cd) and phosphorus (P) form the crystals Cd_3P_2, CdP_2, CdP_4, Cd_7P_{10}, and Cd_6P_7. Only in the first case are the ions assigned the expected chemical valences of Cd^{2+} and P^{3-}.

Among the binary crystals, the easiest structures to visualize are those with equal numbers of the two types of atoms. The structure of sodium chloride is based on a cube. To construct the lattice, the sodium and chlorine atoms are placed on alternate corners of a cube, and the structure is repeated (Figure 7B). The structure of the sodium atoms alone, or the chlorine atoms alone, is fcc and defines the unit cell. The sodium chloride structure thus is made up of two interpenetrating fcc lattices. The cesium chloride lattice (Figure 7A) is based on the bcc structure; every other atom is cesium or chlorine. In this case, the unit cell is a cube. The third important structure for *AB* (binary) lattices is zinc blende (Figure 7D). It is based on the diamond structure, where every other atom is *A* or *B*. Many binary semiconductors have this structure, including those with one atom from the third (boron, aluminum, gallium [Ga], or indium [In]) and one from the fifth (nitrogen, phosphorus, arsenic [As], or antimony [Sb]) column of the periodic table (GaAs, InP, etc.). Most of the chalcogenides (O, S, Se, Te) of cadmium and zinc (CdTe, ZnSe, ZnTe, etc.) also have the zinc blende structure. The mineral zinc blende is ZnS; its unit cell is also fcc. The wurtzite structure is based on the hcp lattice, where every other atom is *A* or *B*. These four structures comprise most of the binary crystals with equal numbers of cations and anions.

The fullerene molecule forms binary crystals M_xC_{60} with alkali atoms, where *M* is potassium (K), rubidium (Rb), or cesium (Cs). The fullerene molecules retain their spherical shape, and the alkali atoms sit between them. The subscript x can take on several values. A compound with $x = 6$ (*e.g.*, K_6C_{60}) is an insulator with the fullerenes in a bcc structure. The case $x = 4$ is an insulator with the body-centred tetragonal structure, while the case $x = 3$ is a metal with the fullerenes in an fcc structure. K_3C_{60}, Rb_3C_{60}, and Cs_3C_{60} are superconductors at low temperatures (see below *Low-temperature phenomena: Superconductivity*).

Alloys

Alloys are solid mixtures of atoms with metallic properties. The definition includes both amorphous and crystalline solids. Although many pairs of elements will mix together as solids, many pairs will not. Almost all chemical entities can be mixed in liquid form. But cooling a

liquid to form a solid often results in phase separation; a polycrystalline material is obtained in which each grain is purely one atom or the other. Extremely rapid cooling can produce an amorphous alloy. Some pairs of elements form alloys that are metallic crystals. They have useful properties that differ from those exhibited by the pure elements. For example, alloying makes a metal stronger; for this reason alloys of gold, rather than the pure metal, are used in jewelry.

Atoms tend to form crystalline alloys when they are of similar size. The sizes of atoms are not easy to define, however, because atoms are not rigid objects with sharp boundaries. The outer part of an atom is composed of electrons in bound orbits; the average number of electrons decreases gradually with increasing distance from the nucleus. There is no point that can be assigned as the precise radius of the atom. Scientists have discovered, however, that each atom in a solid has a characteristic radius that determines its preferred separation from neighbouring atoms. For most types of atom this radius is constant, even in different solids. An empirical radius is assigned to each atom for bonding considerations, which leads to the concept of atomic size. Atoms readily make crystalline alloys when the radii of the two types of atoms agree to within roughly 15 percent.

Two kinds of ordering are found in crystalline alloys. Most alloys at low temperature are binary crystals with perfect ordering. An example is the alloy of copper and zinc. Copper is fcc, whereas zinc is hcp. A 50-percent-zinc–50-percent-copper alloy has a different structure—β-brass. At low temperatures it has the cesium chloride structure: a bcc lattice with alternating atoms of copper and zinc and a cubic unit cell. If the temperature is raised above 470° C, however, a phase transition to another crystalline state occurs. The ordering at high temperature is also bcc, but now each site has equal probability of having a copper or zinc atom. The two types of atoms randomly occupy each site, but there is still long-range order. At all temperatures, thousands of atoms away from a site, the location of the atom site can be predicted with certainty. At temperatures below 470° C one also knows whether that site will be occupied by a copper or zinc atom, while above 470° C there is an equal likelihood of finding either atom. The high-temperature phase is crystalline but disordered. The disorder phase is obtained through a partial melting, not into a liquid state but into a less ordered one. This behaviour is typical of metal alloys. Other common alloys are steel, an alloy of iron and carbon; stainless steel, an alloy of iron, nickel (Ni), and chromium (Cr); pewter and solder, alloys of tin and lead (Pb); and britannia metal, an alloy of tin, antimony, and copper.

Crystal defects

A crystal is never perfect; a variety of imperfections can mar the ordering. A defect is a small imperfection affecting a few atoms. The simplest type of defect is a missing atom and is called a vacancy. Since all atoms occupy space, extra atoms cannot be located at the lattice sites of other atoms, but they can be found between them; such atoms are called interstitials. Thermal vibrations may cause an atom to leave its original crystal site and move into a nearby interstitial site, creating a vacancy-interstitial pair. Vacancies and interstitials are the types of defects found in a pure crystal. In another defect, called an impurity, an atom is present that is different from the host crystal atoms. Impurities may either occupy interstitial spaces or substitute for a host atom in its lattice site.

There is no sharp distinction between an alloy and a crystal with many impurities. An alloy results when a sufficient number of impurities are added that are soluble in the host metal. However, most elements are not soluble in most crystals. Crystals generally can tolerate a few impurities per million host atoms. If too many impurities of the insoluble variety are added, they coalesce to form their own small crystallite. These inclusions are called precipitates and constitute a large defect.

Germanium is a common impurity in silicon. It prefers the same tetrahedral bonding as silicon and readily substitutes for silicon atoms. Similarly, silicon is a common impurity in germanium. No large crystal can be made without impurities: the purest large crystal ever grown was made of germanium. It had about 10^{10} impurities in each cubic centimetre of material, which is less than one impurity for each trillion atoms.

Impurities often make crystals more useful. In the absence of impurities, α-alumina is colourless. Iron and titanium impurities impart to it a blue colour, and the resulting gem-quality mineral is known as sapphire. Chromium impurities are responsible for the red colour characteristic of rubies, the other gem of α-alumina. Pure semiconductors rarely conduct electricity well at room temperatures. Their ability to conduct electricity is caused by impurities. Such impurities are deliberately added to silicon in the manufacture of integrated circuits. In fluorescent lamps the visible light is emitted by impurities in the phosphors (luminescent materials).

Other imperfections in crystals involve many atoms. Twinning is a special type of grain boundary defect, in which a crystal is joined to its mirror image. Another kind of imperfection is a dislocation, which is a line defect that may run the length of the crystal. One of the many types of dislocations is due to an extra plane of atoms that is inserted somewhere in the crystal structure. Another type, called an edge dislocation, is shown in Figure 9. This line defect occurs when there is a missing row of atoms. In the figure the crystal arrangement is perfect on the top and on the bottom. The defect is the row of atoms missing from region *b*. This mistake runs in a line that is perpendicular to the page and places a strain on region *a*.

Dislocations are formed when a crystal is grown, and great care must be taken to produce a crystal free of them. Dislocations are stable and will exist for years. They relieve mechanical stress. If one presses on a crystal, it will accommodate the induced stress by growing dislocations at the surface, which gradually move inward. Dislocations

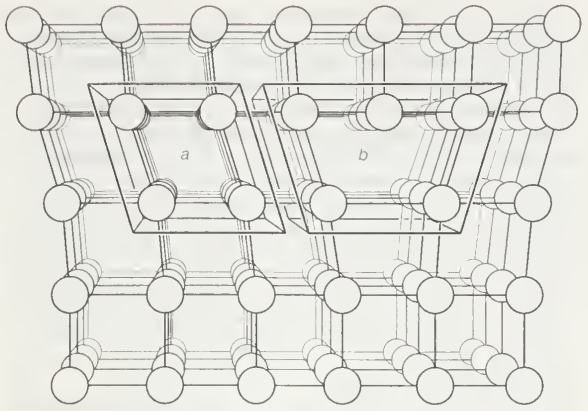

Figure 9: *Crystalline lattice defect.*
An edge dislocation occurs when there is a missing row of atoms as shown in region *b*. Region *a* is strained.

make a crystal mechanically harder. When a metal bar is cold-worked by rolling or hammering, dislocations and grain boundaries are introduced; this causes the hardening.

Determination of crystal structures

Crystal structures are determined by scattering experiments using a portion of the crystal as the target. A beam of particles is sent toward the target, and upon impact some of the particles scatter from the crystal and ricochet in various directions. A measurement of the scattered particles provides raw data, which is then computer-processed to give a picture of the atomic arrangements. The positions are then inferred from the computer-analyzed data.

Max von Laue first suggested in 1912 that this measurement could be done using X rays, which are electromagnetic radiation of very high frequency. High frequencies are needed because these waves have a short wavelength. Von Laue realized that atoms have a spacing of only a few angstroms (1 angstrom [Å] is 10^{-10} metre, or 3.94×10^{-9} inch). In order to measure atomic arrangements, the particles scattering from the target must also have a wavelength of a few angstroms. X rays are required when the beam consists of electromagnetic radiation. The X rays only scatter in certain directions, and there are many X rays associated with each direction. The scattered particles appear in spots corresponding to locations where the scattering from each identical atom produces an outgoing wave that has all the wavelengths in phase. Figure 10 shows incoming waves in phase. The scattering from atom A_2 has a longer path than that from atom A_1. If this additional path has a length $(AB + BC)$ that is an exact multiple of the wavelength, then the two outgoing waves are in phase and reinforce each other. If the scattering angle is changed slightly, the waves no longer add coherently and begin to cancel one another. Combining the scattered radiation from all the atoms in the crystal causes all the outgoing waves to add coherently in certain directions and produce a strong signal in the scattered wave. If the extra path length $(AB + BC)$ is five wavelengths, for example, the spot appears in one place. If it is six wavelengths, the spot is elsewhere. Thus, the different spots correspond to the different multiples of the wavelength of the X ray. The measurement produces two types of information: the directions of the spots and their intensity. This information is insufficient to deduce the exact crystal structure, however, as there is no algorithm by which the computer can go directly from the data to the structure. The crystallographer must propose various structures and compute how they would scatter the X rays. The theoretical results are compared with the measured one, and the theoretical arrangement is chosen that best fits the data. Although this procedure is fast when there are only a few atoms in a unit cell, it may take months or years for complex structures. Some protein molecules, for instance, have hundreds of atoms. Crystals of the proteins are grown, and X rays are used to measure the structure. The goal is to determine how the atoms are arranged in the protein, rather than how the proteins are arranged in the crystal.

Beams of neutrons may also be used to measure crystal structure. The beam of neutrons is obtained by drilling a hole in the side of a nuclear reactor. The energetic neutrons created in nuclear fission escape through the hole. The motion of elementary particles is governed by quantum, or wave, mechanics. Each neutron has a wavelength that depends on its momentum. The scattering directions are determined by the wavelength, as is the case with X rays. The wavelengths for neutrons from a reactor are suitable for measuring crystal structures.

X rays and neutrons provide the basis for two competing technologies in crystallography. Although they are similar in principle, the two methods have some differences. X rays scatter from the electrons in the atoms so that more electrons result in more scattering. X rays easily detect atoms of high atomic number, which have many electrons, but cannot readily locate atoms with few electrons. In hydrogen-bonded crystals, X rays do not detect the protons at all. Neutrons, on the other hand, scatter from the atomic nucleus. They scatter readily from protons and are excellent for determining the structure of hydrogen-bonded solids. One drawback to this method is that some nuclei absorb neutrons completely, and there is little scattering from these targets.

Beams of electrons can also be used to measure crystal structure, because energetic electrons have a wavelength that is suitable for such measurements. The problem with electrons is that they scatter strongly from atoms. Proper interpretation of the experimental results requires that an electron scatter only from one atom and leave the crystal without scattering again. Low-energy electrons scatter many times, and the interpretation must reflect this. Low-energy electron diffraction (LEED) is a technique in which a beam of electrons is directed toward the surface. The scattered electrons that reflect backward from the surface are measured. They scatter many times before leaving backward but mainly leave in a few directions that appear as "spots" in the measurements. An analysis of the varied spots gives information on the crystalline arrangement. Because the electrons are scattered strongly by the atoms in the first few layers of the surface, the measurement gives only the arrangements of atoms in these layers. It is assumed that the same structure is repeated throughout the crystal. Another scattering experiment involves electrons of extremely high energy. The scattering rate decreases as the energy of the electron increases, so that very energetic electrons usually scatter only once. Various electron microscopes are constructed on this principle. A photograph taken by an electron microscope is shown in Figure 11. The bright spots are individual atoms. The dark region on the bottom is a crystal of silicon, and the brighter regions on top are epitaxially grown films of an alloy of germanium and silicon. The arrow points to dislocations formed because of the lattice mismatch.

Electron-diffraction techniques

TYPES OF BONDS

The properties of a solid can usually be predicted from the valence and bonding preferences of its constituent atoms. Four main bonding types are discussed here: ionic, covalent, metallic, and molecular. Hydrogen-bonded solids, such as ice, make up another category that is important in a few crystals. There are many examples of solids that have a single bonding type, while other solids have a mixture of types, such as covalent and metallic or covalent and ionic.

Ionic bonds. Sodium chloride exhibits ionic bonding. The sodium atom has a single electron in its outermost shell, while chlorine needs one electron to fill its outer shell. Sodium donates one electron to chlorine, forming a sodium ion (Na^+) and a chlorine ion (Cl^-). Each ion thus attains a closed outer shell of electrons and takes on a spherical shape. In addition to having filled shells and a spherical shape, the ions of an ionic solid have integer valence. An ion with positive valence is called a cation. In an ionic solid the cations are surrounded by ions with negative valence, called anions. Similarly, each anion is surrounded by cations. Since opposite charges attract, the preferred bonding occurs when each ion has as many neighbours as possible, consistent with the ion radii. Six or eight nearest neighbours are typical; the number depends on the size of the ions and not on the bond angles. The alkali halide crystals are binaries of the *AH* type, where *A* is an alkali ion (lithium [Li], sodium, potassium, rubidium, or cesium) and *H* is a halide ion (fluorine, chlorine, bromine, or iodine). The crystals have ionic bonding, and each ion has six or eight neighbours. Metal ions in the alkaline earth series (magnesium [Mg], calcium [Ca], barium [Ba], and strontium [Sr]) have two electrons in their outer shells and form divalent cations in ionic crystals. The chalcogenides (oxygen, sulfur, selenium, and tellurium) need two electrons to fill their outer *p*-shell. (Electron shells are divided into subshells, designated as *s, p, d, f, g,* and so forth. Each subshell is divided further into orbitals.) Two electrons are transferred from the cations to the anions, leaving each with a closed shell. The alkaline earth chalcogenides form ionic binary crystals such as barium oxide (BaO), calcium sulfide (CaS), barium selenide (BaSe), or strontium oxide (SrO). They have the same structure as sodium chloride, with each atom having six neighbours. Oxygen can be combined with various cations to form a large number of ionically bonded solids.

Covalent bonds. Silicon, carbon, germanium, and a few other elements form covalently bonded solids. In these elements there are four electrons in the outer *sp*-shell, which is half filled. (The *sp*-shell is a hybrid formed from one *s* and one *p* subshell.) In the covalent bond an atom shares one valence (outer-shell) electron with each of its four nearest neighbour atoms. The bonds are highly directional and prefer a tetrahedral arrangement. A covalent bond is formed by two electrons—one from each atom—located in orbitals between the ions. Insulators, in contrast, have all their electrons within shells inside the atoms.

Electron spin

The perpetual spin of an electron is an important aspect of the covalent bond. From a vantage point above the spinning particle, counterclockwise rotation is designated spin-up, while clockwise rotation is spin-down. A fundamental law of quantum physics is the Pauli exclusion principle, which states that no two electrons can occupy the same point in space at the same time with the same direction of spin. In a covalent bond two electrons occupy the same small volume of space (*i.e.*, the same orbital) at all times, so they must have opposite spin: one up and one down. The exclusion principle is then satisfied, and the resulting bond is strong.

In graphite the carbon atoms are arranged in parallel sheets, and each atom has only three near neighbours. The covalent bonds between adjacent carbons within each layer are quite strong and are called σ bonds. The fourth valence electron in carbon has its orbital perpendicular to the plane. This orbital bonds weakly with the similar orbitals on all three neighbours, forming π bonds. The four bonds for each carbon atom in the graphite structure are not arranged in a tetrahedron; three are in a plane. The planar arrangement results in strong bonding, although not as strong as the bonding in the diamond configuration. The bonding between layers is quite weak and arises from the van der Waals interaction; there is much slippage parallel to the layers. Diamond and graphite form an interesting contrast: diamond is the hardest material in nature and is used as an abrasive, while graphite is used as a lubricant.

Besides the elemental semiconductors, such as silicon and germanium, some binary crystals are covalently bonded. Gallium has three electrons in the outer shell, while arsenic lacks three. Gallium arsenide (GaAs) could be formed as an insulator by transferring three electrons from gallium to arsenic; however, this does not occur. Instead, the bonding is more covalent, and gallium arsenide is a covalent semiconductor. The outer shells of the gallium atoms contribute three electrons, and those of the arsenic atoms contribute five, providing the eight electrons needed for four covalent bonds. The centres of the bonds are not at the midpoint between the ions but are shifted slightly toward the arsenic. Such bonding is typical of the III–V semiconductors—*i.e.*, those consisting of one element from the third column of the periodic table and one from the fifth column. Elements from the third column (boron, aluminum, gallium, and indium) contribute three electrons, while the fifth-column elements (nitrogen, phosphorus, arsenic, and antimony) contribute five electrons. All III–V semiconductors are covalently bonded and typically have the zinc blende structure with four neighbours per atom. Most common semiconductors favour this arrangement.

Bonding in binary semiconductors

The factor that determines whether a binary crystal will act as an insulator or a semiconductor is the valence of its constituent atoms. Ions that donate or accept one or two valence electrons form insulators. Those that have three to five valence electrons tend to have covalent bonds and form semiconductors. There are exceptions to these rules, however, as is the case with the IV–VI semiconductors such as lead sulfide. Heavier elements from the fourth column of the periodic table (germanium, tin, and lead) combine with the chalcogenides from the sixth row to form good binary semiconductors such as germanium telluride (GeTe) or tin sulfide (SnS). They have the sodium chloride structure, where each atom has six neighbours. Although not tetrahedrally bonded, they are good semiconductors.

Filled atomic shells with *d*-orbitals have an important role in covalent bonding. Electrons in atomic orbits have angular momentum (L), which is quantized in integer (n) multiples of Planck's constant h: $L = nh$. Electron orbitals with $n = 0$ are called *s*-states, with $n = 1$ are *p*-states, and with $n = 2$ are *d*-states. Silver and copper ions have one valence electron outside their closed shells. The outermost filled shell is a *d*-state and affects the bonding. Eight binary crystals are formed from the copper and silver

halides. Three (AgF, AgCl, AgBr) have the sodium chloride structure with six neighbours. The other five (AgI, CuF, CuCl, CuBr, CuI) have the zinc blende structure with four neighbours. The bonding in this group of solids is on the borderline between covalent and ionic, since the crystals prefer both types of bonds. The alkali metal halides exhibit somewhat different behaviour. The alkali metals are also monovalent cations, but their halides are strictly ionic. The difference in bonding between the alkali metals on the one hand and silver and copper on the other hand is that silver and copper have filled *d*-shells while the alkalis have filled *p*-shells. Since the *d*-shells are filled, they do not covalently bond. This group of electrons is, however, highly polarizable, which influences the bonding of the valence electrons. Similar behaviour is found for zinc and cadmium, which have two valence electrons outside a filled *d*-shell. They form binary crystals with the chalcogenides, which have tetrahedral bonding. In this case the covalent bonding seems to be preferred over the ionic bond. In contrast, the alkaline earth chalcogenides, which are also divalent, have outer *p*-shells and are ionic. The zinc and cadmium chalcogenides are covalent, as the outer *d*-shell electrons of the two cations favour covalent bonding.

Metallic bonds. Metallic bonds fall into two categories. The first is the case in which the valence electrons are from the *sp*-shells of the metal ions; this bonding is quite weak. In the second category the valence electrons are from partially filled *d*-shells, and this bonding is quite strong. The *d*-bonds dominate when both types of bonding are present.

The simple metals are bonded with *sp*-electrons. The electrons of these metal atoms are in filled atomic shells except for a few electrons that are in unfilled *sp*-shells. The electrons from the unfilled shells are detached from the metal ion and are free to wander throughout the crystal. They are called conduction electrons, since they are responsible for the electrical conductivity of metals. Although the conduction electrons may roam anywhere in the crystal, they are distributed uniformly throughout the entire solid. Any large imbalance of charge is prevented by the strong electrical attraction between the negative electrons and the positive ions, plus the strong repulsion between electrons. The phrase electron correlation describes the correlated movements of the electrons; the motion of each electron depends on the positions of neighbouring electrons. Electrons have strong short-range order with one another. Correlation ensures that each unit cell in the crystal has, on the average, the number of electrons needed to cancel the positive charge of the cation so that the unit cell is electrically neutral.

Electron correlation

Cohesive energy is the energy gained by arranging the atoms in a crystalline state, as compared with the gas state. Insulators and semiconductors have large cohesive energies; these solids are bound together strongly and have good mechanical strength. Metals with electrons in *sp*-bonds have very small cohesive energies. This type of metallic bond is weak; the crystals are barely held together. Single crystals of simple metals such as sodium are mechanically weak. At room temperature the crystals have the mechanical consistency of warm butter. Special care must be used in handling these crystals, because they are easily distorted. Metals such as magnesium or aluminum must be alloyed or polycrystalline to have any mechanical strength. Although the simple metals are found in a variety of structures, most are in one of the three closest-packed structures: fcc, bcc, and hcp. Theoretical calculations show that the cohesive energy of a given metal is almost the same in each of the different crystal arrangements; therefore, crystal arrangements are unimportant in metals bound with electrons from *sp*-shells.

A different type of metallic bonding is found in transition metals, which are metals whose atoms are characterized by unfilled *d*-shells. The *d*-orbitals are more tightly bound to an ion than the *sp*-orbitals. Electrons in *d*-shells do not wander away from the ion. The *d*-orbitals form a covalent bond with the *d*-orbitals on the neighbouring atoms. The bonding of *d*-orbitals does not occur in a tetrahedral arrangement but has a different directional preference. In metals the bonds from *d*-orbitals are not completely filled with electrons. This situation is different from the tetrahedral bonds in semiconductors, which are filled with eight electrons. In transition metals the covalent bonds formed with the *d*-electrons are much stronger than the weak bonds made with the *sp*-electrons of simple metals. The cohesive energy is much larger in transition metals. Titanium, iron, and tungsten, for example, have exceptional mechanical strength. Crystal arrangements are important in the behaviour of the transition metals and occur in the close-packed fcc, bcc, or hcp arrangements.

Molecular binding. The Dutch physicist Johannes D. van der Waals first proposed the force that binds molecular solids. Any two atoms or molecules have a force of attraction (F) that varies according to the inverse seventh power of the distance R between the centres of the atoms or molecules: $F = -C/R^7$, where C is a constant. The force, known as the van der Waals force, declines rapidly with the distance R and is quite weak. If the atoms or molecules have a net charge, there is a strong force whose strength varies according to Coulomb's law as the inverse second power of the separation distance: $F = -C'/R^2$, where C' is a constant. This force provides the binding in ionic crystals and some of the binding in metals. Coulomb's law does not apply to atoms or molecules without a net charge. Molecules with a dipole moment, such as water, have a strong attractive force owing to the interactions between the dipoles. For atoms and molecules with neither net charges nor dipole moments, the van der Waals force provides the crystal binding. The force of gravity also acts between neutral atoms and molecules, but it is far too weak to bind molecules into crystals.

The van der Waals force

The van der Waals force is caused by quantum fluctuations. Two neighbouring atoms that are each fluctuating can lower their joint energy by correlating their fluctuations. The van der Waals force arises from correlations in their dipole fluctuations. Electrons bound in atomic orbits are in constant motion around the nucleus, and the distribution of charges in the atom changes constantly as the electrons move, owing to quantum fluctuations. One fluctuation might produce a momentary electric dipole moment (*i.e.*, a separation of charges) on an atom if a majority of its electrons are on one side of the nucleus. The dipole moment creates an electric field on a neighbouring atom; this field will induce a dipole moment on the second atom. The two dipoles attract one another via the van der Waals interaction. Since the force depends on the inverse seventh power of the distance, it declines rapidly with increasing distance. Atoms have a typical radius of one to three angstroms. The van der Waals force binds atoms and molecules within a few angstroms of each other; beyond that distance the force is negligible. Although weak, the van der Waals force is always present and is important in cases where the other forces are absent.

Hydrogen is rarely found as a single atom. Instead it forms diatomic molecules (H_2), which are gaseous at room temperature. At lower temperatures the hydrogen becomes a liquid and at about 20 K turns into a solid. The molecule retains its identity in the liquid and solid states. The solid exists as a molecular crystal of covalently bound H_2 molecules. The molecules attract one another by van der Waals forces, which provide the crystal binding. Helium, the second element in the periodic table, has two electrons, which constitute a filled atomic shell. In its liquid and solid states, the helium atoms are bound together by van der Waals forces. In fact, all the rare gases (helium, neon, argon, krypton, and xenon) are molecular crystals with the binding provided by van der Waals forces.

Many organic molecules form crystals where the molecules are bound by van der Waals forces. In methane (CH_4), a central carbon makes a covalent bond with each hydrogen atom, forming a tetrahedron. In crystalline methane the molecules are arranged in the fcc structure. Benzene (C_6H_6) has the carbon atoms in a hexagonal ring; each carbon has three coplanar σ bonds, as in graphite, where two bonds are with neighbouring carbon atoms and the third bond is with a hydrogen atom. Crystalline benzene has four molecules per unit cell in a complex arrangement. Fullerene and the rare gas atoms are spherical, and the crystalline arrangement corresponds to the closest

Bonding in crystals of organic molecules

packing of spheres. Most organic molecules, however, are not spherical and display irregular shapes. For odd-shaped molecules, the van der Waals interaction depends on the rotational orientation of the two molecules. In order to maximize the force, the molecules in the crystal have unusual arrangements, as in the case of benzene.

Hydrogen bonding. Hydrogen bonding is important in a few crystals, notably in ice. With its lone electron, a hydrogen atom usually forms a single covalent bond with an electronegative atom. In the hydrogen bond the atom is ionized to a proton. The proton sits between two anions and joins them. Hydrogen bonding occurs with only the most electronegative ions: nitrogen, oxygen, and fluorine. In water the hydrogen links pairs of oxygen ions. Water is found in many different crystal structures, but they all have the feature that the hydrogen atoms sit between pairs of oxygen. Another hydrogen-bonded solid is hydrogen fluoride (HF), in which the hydrogen atom (proton) links pairs of fluorines.

CRYSTAL GROWTH

The earliest crystal grower was nature. Many excellent crystals of minerals formed in the geologic past are found in mines and caves throughout the world. Most precious and semiprecious stones are well-formed crystals. Early efforts to produce synthetic crystals were concentrated on making gems. Synthetic ruby was grown by the French scientist Marc Antoine Augustin Gaudin in 1873. Since about 1950 scientists have learned to grow in the laboratory crystals of quality equal or superior to those found in nature. New techniques for growth are continually being developed, and crystals with three or more atoms per unit cell are continually being discovered.

Vapour growth. Crystals can be grown from a vapour when the molecules of the gas attach themselves to a surface and move into the crystal arrangement. Several important conditions must be met for this to occur. At constant temperature and equilibrium conditions, the average number of molecules in the gas and solid states is constant: molecules leave the gas and attach to the surface at the same rate that they leave the surface to become gas molecules. For crystals to grow, the gas-solid chemical system must be in a nonequilibrium state such that there are too many gaseous molecules for the conditions of pressure and temperature. This state is called supersaturation. Molecules are more prone to leave the gas than to rejoin it, so they become deposited on the surface of the container. Supersaturation can be induced by maintaining the crystal at a lower temperature than the gas. A critical stage in the growth of a crystal is seeding, in which a small piece of crystal of the proper structure and orientation, called a seed, is introduced into the container. The gas molecules find the seed a more favourable surface than the walls and preferentially deposit there. Once the molecule is on the surface of the seed, it wanders around this surface to find the preferred site for attachment. Growth proceeds one molecule at a time and one layer at a time. The process is slow; it takes days to grow a small crystal. Crystals are grown at temperatures well below the melting point to reduce the density of defects. The advantage of vapour growth is that very pure crystals can be grown by this method, while the disadvantage is that it is slow.

Seeding

Most clouds in the atmosphere are ice crystals that form by vapour growth from water molecules. Most raindrops are crystals as they begin descending but thaw during their fall to Earth. Seeding for rain—accomplished by dropping silver iodide crystals from airplanes—is known to induce precipitation. In the laboratory, vapour growth is usually accomplished by flowing a supersaturated gas over a seed crystal. Quite often a chemical reaction at the surface is needed to deposit the atoms. Crystals of silicon can be grown by flowing chlorosilane ($SiCl_4$) and hydrogen (H_2) over a seed crystal of silicon. Hydrogen acts as the buffer gas by controlling the temperature and rate of flow. The molecules dissociate on the surface in a chemical reaction that forms hydrogen chloride (HCl) molecules. Hydrogen chloride molecules leave the surface, while silicon atoms remain to grow into a crystal. Binary crystals such as gallium arsenide (GaAs) are grown by a similar method. One process employs gallium chloride (GaCl) as the gallium carrier. Arsenic is provided by molecules such as arsenous chloride ($AsCl_3$), arsine (AsH_3), or As_4 (yellow arsenic). These molecules, with hydrogen as the buffer gas, grow crystals of gallium arsenide while forming gas molecules such as gallium trichloride ($GaCl_3$) and hydrogen chloride. Trimethylgallium, $(CH_3)_3Ga$, is another molecule that can be used to deliver gallium to the surface.

Growth from solution. Large single crystals may be grown from solution. In this technique the seed crystal is immersed in a solvent that contains typically about 10–30 percent of the desired solute. The choice of solvent usually depends on the solubility of the solute. The temperature and pH (a measure of acidity or basicity) of the solution must be well controlled. The method is faster than vapour growth, because there is a higher concentration of molecules at the surface in a liquid as compared to a gas, but it is still relatively slow.

Growth from the melt. This method is the most basic. A gas is cooled until it becomes a liquid, which is then cooled further until it becomes a solid. Polycrystalline solids are typically produced by this method unless special techniques are employed. In any case, the temperature must be controlled carefully. Large crystals can be grown rapidly from the liquid elements using a popular method invented in 1918 by the Polish scientist Jan Czochralski and called crystal pulling. One attaches a seed crystal to the bottom of a vertical arm such that the seed is barely in contact with the material at the surface of the melt. A modern Czochralski apparatus is shown in Figure 12A. The arm is raised slowly, and a crystal grows underneath at the interface between the crystal and the melt. Usually the crystal is rotated slowly, so that inhomogeneities in the liquid are not replicated in the crystal. Large-diameter crystals of silicon are grown in this way for use as computer chips. Based on measurements of the weight of the crystal during the pulling process, computer-controlled apparatuses can vary the pulling rate to produce any de-

Crystal pulling

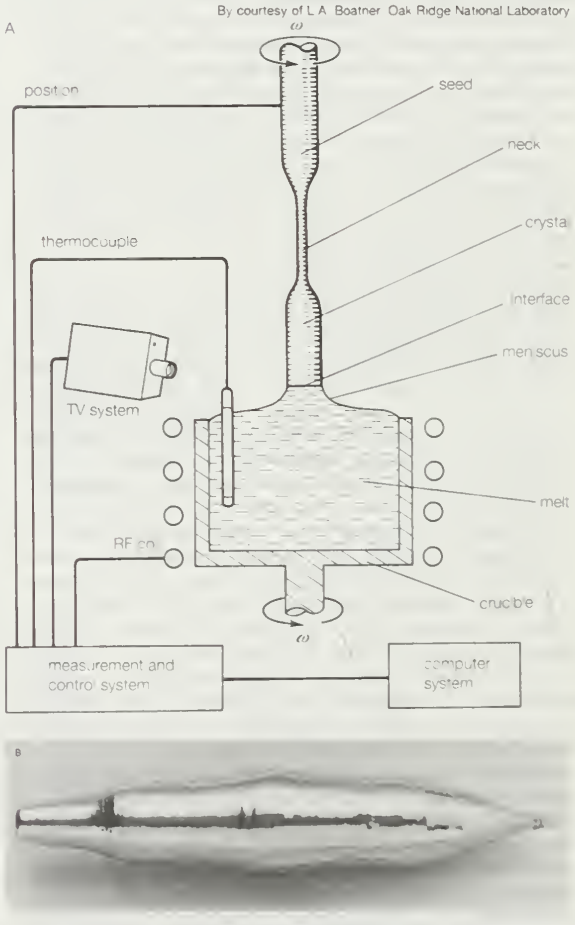

Figure 12: *Crystal pulling using the Czochralski method.* (A) A schematic view of a modern apparatus. (B) A crystal of stainless steel grown by this method.

sired diameter. Crystal pulling is the least expensive way to grow large amounts of pure crystal. A photograph of a single crystal of stainless steel grown by the Czochralski method is shown in Figure 12B. The original seed is on the right tip. Binary crystals can also be pulled; for example, synthetic sapphire crystals can be pulled from molten alumina. Special care is required to grow binary and other multicomponent crystals; the temperature must be precisely controlled because such crystals may be grown only at a single, extremely high temperature. The melt has a tendency to be inhomogeneous, since the two liquids may try to separate by gravity.

The Bridgman method (named after the American scientist Percy Williams Bridgman) is also widely used for growing large single crystals. The molten material is put into a crucible, often of silica, which has a cylindrical shape with a conical lower end. Heaters maintain the molten state. As the crucible is slowly lowered into a cooler region, a crystal starts growing in the conical tip. The crucible is lowered at a rate that matches the growth of the crystal, so that the interface between crystal and melt is always at the same temperature. The rate of moving the crucible depends on the temperature and the material. When done successfully, the entire molten material in the crucible grows into a single large crystal. One disadvantage of the method is that excess impurities are pushed out of the crystal during growth. A layer of impurities grows at the interface between melt and solid as this surface moves up the melt, and the impurities become concentrated in the higher part of the crystal.

Epitaxy

Epitaxy is the technique of growing a crystal, layer by layer, on the atomically flat surface of another crystal. In homoepitaxy a crystal is grown on a substrate of the same material. Silicon layers of different impurity content, for example, are grown on silicon substrates in the manufacture of computer chips. Heteroepitaxy, on the other hand, is the growth of one crystal on the substrate of another. Silicon substrates are often used since they are readily available in atomically smooth form. Many different semiconductor crystals can be grown on silicon, such as gallium arsenide, germanium, cadmium telluride (CdTe), and lead telluride (PbTe). Any flat substrate can be used for epitaxy, however, and insulators such as rock salt (NaCl) and magnesium oxide (MgO) are also used.

Molecular-beam epitaxy, commonly abbreviated as MBE, is a form of vapour growth. The field began when the American scientist John Read Arthur reported in 1968 that gallium arsenide could be grown by sending a beam of gallium atoms and arsenic molecules toward the flat surface of a crystal of the molecule. The amount of gas molecules can be controlled to grow just one layer, or just two, or any desired amount. This method is slow, since molecular beams have low densities of atoms. Chemical vapour deposition (CVD) is another form of epitaxy that makes use of the vapour growth technique. Also known as vapour-phase epitaxy (VPE), it is much faster than MBE since the atoms are delivered in a flowing gas rather than in a molecular beam. Synthetic diamonds are grown by CVD. Rapid growth occurs when methane (CH_4) is mixed with atomic hydrogen gas, which serves as a catalyst. Methane dissociates on a heated surface of diamond. The carbon remains on the surface, and the hydrogen leaves as a molecule. Growth rates are several micrometres (1 micrometre is equal to 0.00004 inch) per hour. At that rate, a stone 1 centimetre (0.4 inch) thick is grown in 18 weeks. CVD diamonds are of poor quality as gemstones but are important electronic materials. Because hydrogen is found in nature as a molecule rather than as a single atom, making atomic hydrogen gas is the major expense in growing CVD diamonds. Liquid-phase epitaxy (LPE) uses the solution method to grow crystals on a substrate. The substrate is placed in a solution with a saturated concentration of solute. This technique is used to grow many crystals employed in modern electronics and optoelectronic devices, such as gallium arsenide, gallium aluminum arsenide, and gallium phosphide.

An important concern in successful epitaxy is matching lattice distances. If the spacing between atoms in the substrate is close to that of the top crystal, then that crystal will grow well; a small difference in lattice distance can be accommodated as the top crystal grows. When the lattice distances are different, however, the top crystal becomes deformed, since structural defects such as dislocations appear (see Figure 9). Although few crystals share the same lattice distance, a number of examples are known. Aluminum arsenide and gallium arsenide have the same crystal structure and the same lattice parameters to within 0.1 percent; they grow excellent crystals on one another. Such materials, known as superlattices, have a repeated structure of n layers of GaAs, m layers of AlAs, n layers of GaAs, m layers of AlAs, and so forth. Superlattices represent artificially created structures that are thermodynamically stable; they have many applications in the modern electronics industry. Another lattice-matched epitaxial system is mercury telluride (HgTe) and cadmium telluride (CdTe). These two semiconductors form a continuous semiconductor alloy $Cd_xHg_{1-x}Te$, where x is any number between 0 and 1. This alloy is used as a detector of infrared radiation and is incorporated in particular in night-vision goggles.

Superlattices

Dendritic growth. At slow rates of crystal growth, the interface between melt and solid remains planar, and growth occurs uniformly across the surface. At faster rates of crystal growth, instabilities are more likely to occur; this leads to dendritic growth. Solidification releases excess energy in the form of heat at the interface between solid and melt. At slow growth rates, the heat leaves the surface by diffusion. Rapid growth creates more heat, which is dissipated by convection (liquid flow) when diffusion is too slow. Convection breaks the planar symmetry so that crystal growth develops along columns, or "fingers," rather than along planes. Each crystal has certain directions in which growth is fastest, and dendrites grow in these directions. As the columns grow larger, their surfaces become flatter and more unstable. Columns start growing from other columns in the pattern shown in Figure 13. This feather or tree structure is characteristic of dendritic growth. Snowflakes are an example of crystals that result from dendritic growth.

ELECTRIC PROPERTIES

The German physicist Georg Simon Ohm discovered the basic law of electric conduction, which is now called Ohm's law. His law relates the voltage (V, measured in volts), the current (I, in amperes), and the resistance (R, in ohms) according to the formula $V = RI$. A current

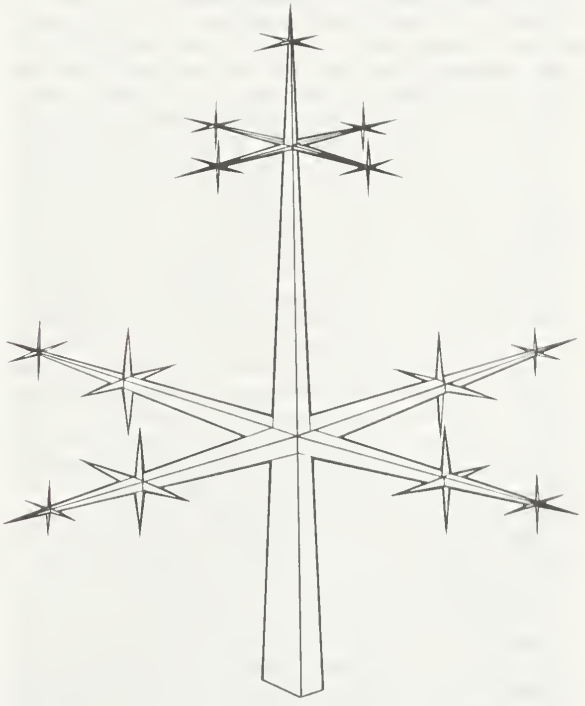

Figure 13: A possible pattern during dendritic growth of crystals.

I through a solid induces a voltage V; the resistance R is the constant of proportionality. The value of R is an important factor in the design of electrical circuits. It is determined by the shape of the resistor: a long narrow object has more resistance than a short wide one of the same material. For solids, the important parameter is the resistivity ρ, which is given in units of ohm-metres. It is the resistivity per volume unit and is independent of shape. The relationship between R and ρ is $R = \rho L/A$, where A is the area of the resistor and L is the length. These dimensions are measured in the direction of the current: L is the length of the current path, and A is the cross-sectional area. The resistance of a copper bar depends on its shape, but at a given temperature every piece of pure copper has the same resistivity. Thus the resistivity is a fundamental parameter of a material and is investigated by scientists. Resistivities of solids span a wide range of values. Certain metals have zero resistivity at low temperatures; they are called superconductors. At the other extreme, very good insulators such as sulfur and polystyrene have resistivities larger than one quadrillion ohm-metres. At room temperature, the metal with the lowest value of resistivity is silver, with $\rho = 1.6 \times 10^{-8}$ ohm-metre; the second best conductor is copper, with $\rho = 1.7 \times 10^{-8}$ ohm-metre. Copper, rather than silver, is used in household wires because of the high cost of silver.

Electrical conductivity σ is the inverse of resistivity and is measured in units of ohm-metre^{-1}. Electrical current is produced by the motion of charges. In crystals, electrical current is due to the motion of both ions and electrons.

Ion hopping

Ions move by hopping occasionally from site to site; all solids can conduct electricity in this manner. When the voltage is zero, there is no net current because the ions hop randomly in all directions. The imposition of a small voltage causes the ions to slightly favour one direction of motion, which leads to a net flow of charge in that direction; this constitutes an electrical current. The electricity conducted by this process is quite small and is usually negligible compared with that carried by the electrons. When an ion hops, it must migrate to a vacant site, which could be either an interstitial or a vacancy. Ionic conductivity can occur because hopping ions cause vacancies to move through the solid. An ion hops to the vacant site, thereby filling the vacancy, while creating a new one at the ion's former site. Repeating this process causes the position of the vacancy to migrate through the crystal. The motion of the vacancy arises from the motion of ions, which carry charge and contribute to electrical conductivity.

Ion hops are induced by thermal fluctuations. Most of the ions move within their lattice site, vibrating around this point. Temperature is defined as the average energy of this vibrational motion; the more the ions move, the higher the temperature. An individual ion at times moves slowly and at times vibrates quite rapidly but usually has an energy near the average value. Each ion shares its vibrational energy with its neighbouring ions. An ion typically has some neighbours with small vibrations and others with large ones. The average energy shared with the neighbours is close to the average energy of all the atoms. As a random process, however, it occasionally happens that all neighbours of an ion may have large vibrations, in which case the ion will acquire an unusually high energy. This energy may be high enough to cause it to leave its site and hop to a neighbouring site. A thermal fluctuation is the rare process in which the energy at a local site may be much higher or lower than the average energy in the crystal. Probability theory shows that the higher the temperature, the more frequent are these thermal fluctuations. Ions therefore hop more often at high temperature.

A few solids conduct electricity better by ion motion than by electron motion. These unusual materials are technologically important in making batteries. All batteries have two electrodes separated by an electrolyte, which is a material that conducts ions better than electrons. An example of a crystal electrolyte is β-alumina, which readily conducts monovalent cations such as silver (Ag^+) and sodium (Na^+). Among all ions, silver has the largest value of ionic conductivity in many different electronic insulators. The copper ion (Cu^+) forms the same type of chemical bonds as does the silver ion, but the copper ion, because of its smaller radius, does not migrate as well within an electrolyte. Silver ions fit perfectly into the interstitial sites of the crystal lattices of several electrolytes, while the smaller copper ions permit the neighbouring ions to collapse around them, inhibiting further hopping. There are a few good conductors of the inexpensive copper ion that can be used as solid electrolytes in batteries. Silver is too costly and heavy to use in large-volume batteries such as those found in automobiles, but it is used in the smaller batteries that power devices such as hearing aids.

Electrons carry the basic unit of charge e, equal to 1.6022×10^{-19} coulomb. They have a small mass and move rapidly. Most electrons in solids are bound to the atoms in local orbits, but a small fraction of the electrons are available to move easily through the entire crystal. These so-called conduction electrons carry the electrical current. Solids with many conduction electrons are metals, while those with a few are semimetals or semiconductors. In insulators, nearly all the electrons are bound, and very few electrons are capable of carrying current. A typical metal has one or more conduction electrons in each atomic unit cell, a semiconductor may have only one conduction electron for each thousand unit cells, and an insulator may have one conduction electron per one million or one trillion unit cells.

Conduction electrons

The bonding properties of the individual atoms of a solid determine the behaviour of the bulk solid. The electrical properties of a solid can usually be predicted from the valence and bonding preferences of its atoms. In the argon atom, for example, all atomic shells are filled with electrons. The electrons of solid argon remain in the atomic shells; none are conduction electrons, and the electrical resistivity is therefore high. Solid argon, like all the rare gas solids, is a good insulator. A few conduction electrons are contributed by impurities, and so the conductivity, though small, is not zero. These conduction electrons move quite readily through the solid. The term mobility is used to describe how well a conduction electron moves through the solid in response to a voltage. Conductivity is the product of mobility, the electrical charge e, and the number N of conduction electrons per unit volume: $\sigma = Ne\mu$, where σ is the conductivity and μ is the mobility. The mobility of the rare gas solids is high, but their conductivity is nonetheless low because there is a small number of conduction electrons.

Like the rare gas solids, most ionic solids are electrical insulators. In sodium chloride, for example, each sodium atom donates its single valence electron to a chlorine atom, thus forming a solid composed of Na^+ and Cl^- ions. All electrons are in filled shells at low temperature, and in a perfect crystal there are no conduction electrons. Sodium chloride is thus an insulator with a very high resistivity. Some conduction electrons are provided by impurities or thermal excitations. At high temperatures large ion vibrations from thermal fluctuations may knock an electron out of a filled shell, upon which it becomes a conduction electron and contributes to the conductivity. The number of conduction electrons created by thermal excitations is small for most insulators. Although defects can be responsible for producing conduction electrons, they can also destroy the conducting ability of electrons by trapping them. The defects have local orbitals that provide a lower energy state for the electron than the one occupied in the conduction state. A conduction electron becomes bound at the defect, ceasing to contribute to the conductivity. This process is very efficient in insulators, so the few conduction electrons provided by impurities and thermal fluctuations are usually trapped at other defects. By definition, an insulator is a solid that does not provide a stable environment for conduction electrons.

Metals have a high density of conduction electrons. The aluminum atom has three valence electrons in a partially filled outer shell. In metallic aluminum the three valence electrons per atom become conduction electrons. The number of conduction electrons is constant, depending on neither temperature nor impurities. Metals conduct electricity at all temperatures, but for most metals the conductivity is best at low temperatures. Divalent atoms, such

as magnesium or calcium, donate both valence electrons to become conduction electrons, while monovalent atoms, such as lithium or gold, donate one. As will be recalled, the number of conduction electrons alone does not determine conductivity; it depends on electron mobility as well. Silver, with only one conduction electron per atom, is a better conductor than aluminum with three, for the higher mobility of silver compensates for its fewer electrons.

Sommerfeld model of metals

In metals such as sodium and aluminum, the atoms donate all their valence electrons to the conduction band. The resulting ions are small, occupying only 10–15 percent of the volume of the crystal. The conduction electrons are free to roam through the remaining space. A simple model, which often describes well the properties of the conduction electrons, treats them as interacting neither with the ions nor with each other. The electrons are approximated as free particles wandering easily through the crystal. This concept was first proposed by the German scientist Arnold Johannes Wilhelm Sommerfeld. It works quite well for those metals, known as simple metals, whose conduction electrons are donated from *sp*-shells—for example, aluminum, magnesium, calcium, zinc, and lead. They are called simple because they are aptly described by the simple theory of Sommerfeld.

The transition metals are found in three rows of the periodic table: the first row consists of scandium through nickel, the second row is yttrium through palladium, and the third row is lanthanum plus hafnium through platinum. Within these rows, as the atomic number increases, the electrons fill *d*-states in the outer shell of the atom. In crystal form the transition metal atoms are metals with interesting properties. The *d*-electrons are more tightly bound to the ion centre than are *sp*-electrons. While the *sp*-valence electrons become conduction electrons that move freely through the crystal, the *d*-electrons tend to stay localized near the ion. Neighbouring ions may covalently bond *d*-electrons. In most cases, these *d*-states are only partially filled. Electrons in these *d*-states can conduct as well as those in the *sp*-states, but the electron motion in the *d*-states is not well approximated by the Sommerfeld model of free particles. Instead, the electrons move from ion to ion through the shared covalent bonds of the *d*-electrons. These metals have some conduction electrons donated from *sp*-states and others from *d*-states; therefore, some electrons move freely according to the Sommerfeld model, while others move through the bonds. Each electron switches back and forth between these two modes of conduction, resulting in electron motion that is quite complicated.

An applied voltage causes the electrons of metals to accelerate and contribute to the electric current. The electrons scatter occasionally from imperfections in the crystal, and the rate of scattering determines the mobility. The electrons do not scatter from the ions in the crystal that are located at the expected site in the crystal lattice. The electrons move to accommodate the host ions rather than scatter from them. If an ion is missing, misplaced, or of a different species, however, the electron will scatter from this defect. Ions vibrate around their lattice site, with the amplitude vibration increasing with temperature. The vibration may cause the ion to be displaced from its crystal site, providing a defect from which an electron will scatter. The resistivity of metals increases at high temperature, owing to the increase in vibrations of the ions in the crystal and the resulting increase in scattering.

Conducting properties of semiconductors

Semiconductors have conducting properties intermediate to those of insulators and metals. In some cases the semiconductors are insulators, while in others they are metals. Semiconductors share with insulators the property that they have no conduction electrons in a perfect crystal without thermal fluctuations. Conduction electrons are provided by electrons from impurities or by thermal fluctuation of electrons from atomic shells. The important difference between insulators and semiconductors is in the nature of the traps. A trap is a local electron energy state at a defect. Although the traps in insulators bind conduction electrons tightly, those in semiconductors only weakly bind the electrons. A trapped conduction electron in a semiconductor can be kicked back to the conduction band by thermal fluctuations. At room temperature, the majority of extra electrons are found in the conduction band rather than in traps. The inability of traps to keep electrons is the main difference between semiconductors and insulators. A semiconductor at room temperature has a sufficient number of conduction electrons to provide good electrical conductivity. Since the mobility of electrons in many semiconductors is exceptionally high, even a small number of conduction electrons is generally sufficient to allow high conductivity.

Phosphorus has five valence electrons, while silicon has four. When a phosphorus atom substitutes for an atom in a silicon crystal lattice, four of its five valence electrons enter covalent bonds. The fifth one is extra, sitting in a shallow trap around the phosphorus site. It is easily excited, however, to the conduction band by thermal fluctuations. At room temperature, there is nearly one conduction electron in silicon for each phosphorus impurity. By controlling the number of impurities, it is possible to control the conductivity of silicon. Other substitutional atoms such as arsenic and antimony also serve as electron donors to the conduction band of silicon.

If a sufficient number of conduction electrons are added to a semiconductor through the introduction of impurities, the electrical properties become metallic. There is a critical concentration of impurities N_c, which depends on the type of impurity. For impurity concentrations less than the critical amount N_c, the conduction electrons become bound in traps at extremely low temperatures, and the semiconductor becomes an insulator. For a concentration of impurities higher than N_c, the conduction electrons are not bound in traps at low temperatures, and the semiconductor exhibits metallic conduction. For phosphorus impurities in silicon, $N_c = 2 \times 10^{18}$ impurities per cubic centimetre. Although this number seems large, it represents about one phosphorus atom for each 100,000 silicon atoms. On a percentage basis, a small number of phosphorus atoms will change silicon from an insulator to a metallic conductor. Other semiconductors have similar properties. In gallium arsenide the critical concentration of impurities for metallic conduction is 100 times smaller than in silicon.

Gallium atoms, like those of phosphorus, can be used as substitutional impurities in silicon. Each atom contributes three electrons to covalent bonds. Since four electrons are needed to complete a tetrahedral arrangement, there is one electron absent per gallium atom from a full set of covalent bonds. The missing electron is called a hole.

Conduction by holes

Holes can move around the crystal in a process similar to the motion of ion vacancies, except in this case there is an electron vacancy. An electron from a nearby covalent bond can jump over and fill the empty electron state, thereby moving the hole to the neighbouring bond. The hole contributes a positive charge, since it is the absence of an electron. The mobility of holes in response to an external voltage is almost as high as the mobility of conduction electrons. A semiconductor may have a high density of impurities that cause holes, and a high electrical conductivity is created by their motion. A *p*-type semiconductor is one with a preponderance of holes; an *n*-type semiconductor has a preponderance of conduction electrons. The symbols *p* and *n* come from the sign of the charge of the particles: *p*ositive for holes and *n*egative for electrons.

Thermal fluctuations can excite an electron out of a covalent bond, making it a conduction electron. The bond is left with a missing electron, which constitutes a hole. Thermal fluctuations thus make electron-hole pairs. Usually the electron and hole separate in space, and each wanders away. The Swiss-American scientist Gregory Hugh Wannier first suggested that the electron and hole could bind together weakly. This bound state, called a Wannier exciton, does exist; the hole has a positive charge, the electron has a negative charge, and the opposites attract. The exciton is observed easily in experiments with electromagnetic radiation. It lives for only a short time—between a nanosecond and a microsecond—depending on the semiconductor. The short lifetime is due to the preference for the electron to reenter a covalent bond state, thereby eliminating both the hole and the conduction electron. This

recombination of electron and hole is easily accomplished from the exciton state, since the two particles are spatially nearby. If the electron and hole escape the exciton state by thermal fluctuation, they travel away from each other. Recombination is then less probable, since it occurs only when the wandering particles pass close to one another again. Recombination also can occur at defect sites. First, one particle becomes bound to the defect, followed by the second particle. The electron and hole are again close to one another, and the electron can reoccupy the covalent bond.

As in metals, the mobility of electrons in semiconductors is limited by electron scattering. For crystals with few defects, the mobility is limited by defect scattering at the lowest temperatures and by ion vibrations at moderate and high temperatures. Since semiconductors with few defects have a small number of conduction electrons, the resistivity is high. The number of conduction electrons is increased in semiconductors by adding impurities. Unfortunately, this also increases the scattering from impurities, which reduces the mobility. Figure 14 shows the resistivity of silicon at room temperature ($T = 300$ K) as a function of the concentration of impurities. The two curves represent conduction by electrons and by holes. Each grid mark on the graph is a factor of 10. The resistivity varies by a factor of one million from the lowest to the highest concentration of impurities.

Photoconductivity

Semiconductors with few impurities are good photoconductors. Photoconductivity is the phenomenon in which the electrical conductivity of a solid is increased by exposing it to light. Light is electromagnetic radiation within a specific narrow band of frequencies. The quanta of light are absorbed by the semiconductor, creating electron-hole pairs that provide the electrical conduction. More intense light produces more electron-hole pairs and gives rise to better conductivity. Each semiconductor absorbs light over a specific frequency range, so different semiconductors are used as photoconductors for different ranges of frequency.

Zinc oxide (ZnO) is an interesting material with respect to conductivity. It crystallizes in the wurtzite structure, and its bonding is a mix of ionic and covalent. High-purity single crystals are insulators. Zinc oxide is the most piezoelectric of all materials and is widely used as a transducer in electronic devices. (Piezoelectricity is the property of a crystal to become polarized when subjected to pressure.) Zinc oxide is a good semiconductor when aluminum impurities are included in the crystal. Polycrystalline ceramics of semiconducting zinc oxide conduct well and obey Ohm's law. The addition of small amounts of other oxides, such as those of barium and chromium, causes zinc oxide ceramics to have very nonohmic electrical properties; the electrical current in such ceramics is the most nonlinear of any known material. The current I becomes proportional to a power of the voltage V^n, where the exponent n has values of more than 100 in certain ranges of voltage. This material is called a varistor, which is a contraction of the words variable and resistor. Zinc oxide varistors are widely used as circuit elements to protect against voltage surges. Figure 15 shows a graph of current versus voltage for a zinc oxide varistor used in household electronics. There is little current until a critical voltage of about 330 volts is reached, at which point the current rises steeply in a nonlinear fashion. Another interesting application of zinc oxide was its former use as a white pigment in paint. It has been replaced by titanium dioxide (TiO_2), however, which is whiter.

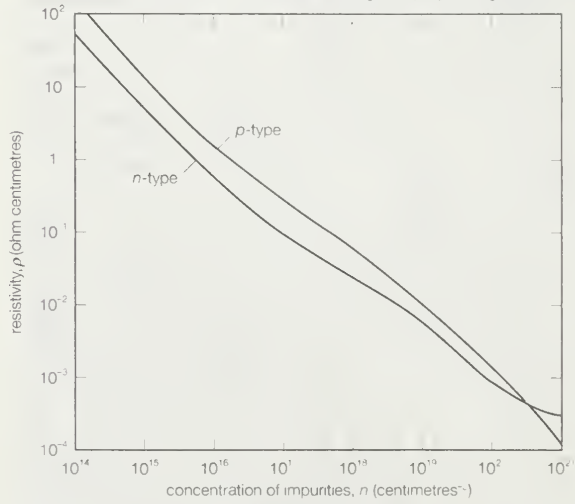

Figure 14: The electrical resistivity (ρ) of a silicon semiconductor at a temperature of 300 K as a function of the concentration of impurities (n).

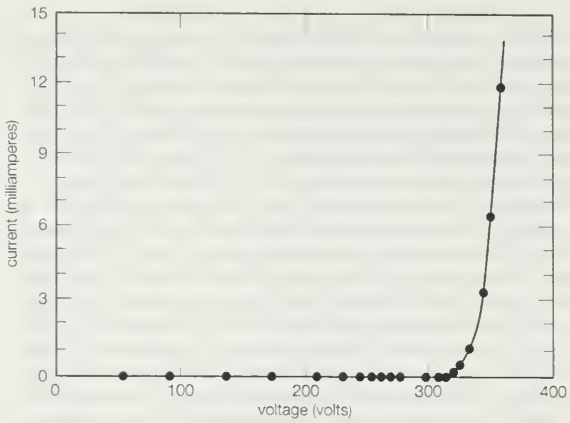

Figure 15: The dependence of current on voltage in a varistor of zinc oxide. The nonlinear behaviour is evident in the sharp upturn in current when the voltage exceeds 330 volts.

MAGNETISM

Electrons are perpetually rotating, and, since the electron has a charge, its spin produces a small magnetic moment. Magnetic moments are small magnets with north and south poles. The direction of the moment is from the south to the north pole. In nonmagnetic materials the electron moments cancel, since there is random ordering to the direction of the electron spins. Whenever two electrons have their moments aligned in opposite directions, their effects tend to cancel. Magnets are formed when a large number of the electrons align their individual moments in the same direction. Only a small percentage of crystals are magnetic. The forces that tend to align the electron spins are subtle. There are three separate parts to the explanation of magnetism. They are as follows:

Formation of magnets

1. Most magnets are composed of atoms whose valence electrons are in d- or f-shells. Atomic shell notation refers to angular momentum, where s has zero unit, p has one, d has two, and f has three. Electrons in d-shells tend to be bound to the ion, and those in f-shells are bound even more tightly.

2. Each electron orbital can be occupied by two electrons—one with spin up and one with spin down. The d-shell has five orbital states and 10 electrons when filled; the f-shell has seven orbital states and 14 electrons when filled. Electrons are added one at a time to the d-states according to the empirical rule that the electrons arrange themselves in the state with the maximum spin and the maximum magnetic moment. If the first electron has spin up, the next four will also have spin up. A maximum of five electrons with spin up are allowed in the d-shell, so the sixth must have spin down. Similarly, the f-shell accepts seven electrons with the same direction of spin before taking electrons with the opposite spin orientation. The order in which electrons fill atomic shells is described by Hund's rules, of which the first is maximizing the total spin. Atoms with electrons in partially filled d- and f-shells usually have a nonzero total spin and thus a net magnetic moment. These magnetic ions are the building blocks for magnetic crystals.

Hund's first rule is due to a phenomenon called electron exchange. As discussed above, a fundamental rule of quantum mechanics, the Pauli exclusion principle, states

that no two electrons with the same direction of spin can occupy the same point in space at the same time. Electrons have charge and repel one another. If two electrons come close together, a large amount of repulsive energy is produced. Physical systems prefer the state of lowest energy, and so electrons avoid such close approach. When their spins are parallel, electrons avoid each other because of the Pauli principle. Electrons in the same shell thus prefer to have their spins parallel, since this configuration keeps the electrons apart and thereby reduces the amount of repulsive energy. The concept of electron exchange is the basis of magnetism. It explains why ions such as iron have large magnetic moments. In divalent iron (Fe^{2+}) the six *d*-electrons are arranged to achieve maximum electron spin and magnetic moment.

3. Individual ions with fixed magnetic moments may cooperatively align their moments, resulting in the presence of magnetic properties of the crystal as a whole.

Ferromagnetic materials

Ferromagnet crystals have the magnetic moments from all their constituent ions aligned in the same direction; the magnetic moment of the crystal is the summation of the individual moments of the ions. There must be a magnetic force between the different ions that causes them to cooperatively align their moments. This force is also due to electron exchange. The *d*-orbitals from neighbouring ions overlap weakly into covalent bonds. The *d*-electrons on the separate ions are shared with the neighbour through covalent bonding. The electron exchange will tend to align the spins on the two neighbours. Aligning all pairs of neighbours aligns all ions. The exchange force between neighbours is much weaker than the force within the atomic shell of one ion. Although weak, the force is sufficient to cause ferromagnetism.

Iron is a typical ferromagnet. Not all bars of iron are magnets; the existence of magnetism is determined by the nature of the domains within the bar. A domain is a region of a crystal in which all the ions are ferromagnetically aligned in the same direction. A bar may be composed of many domains, each having a different magnetic orientation. Such a bar would not appear to be magnetic. Each piece of the bar is magnetic, but the domains have moments that point in different directions, so the bar has no net moment. If the bar of iron is placed in a strong magnetic field, however, the bar becomes magnetic. The field causes the bar to become a single domain with all moments aligned along the external field. The domains do not rotate their moments; instead, the walls between domains move. The domain with a moment along the field grows, while the others become smaller. If removed from the magnetic field, the iron bar will remain magnetized for a considerable time period. Nearly all bars of iron are polycrystalline: they have many small grains of single crystals, which are packed together with random orientation. A grain could be a single domain, a domain could include many grains, or a large grain could have several domains.

Ferromagnetic materials change their magnetic ordering at a characteristic temperature T_c called the Curie temperature. The Curie temperatures for three common ferromagnetics—iron, cobalt, and nickel—are 1,043 K; 1,394 K; and 631 K, respectively. For temperatures below T_c the magnetic moments of the ions are aligned and the crystal is magnetic. For temperatures above T_c the crystal is not ferromagnetic, since the individual atomic moments are no longer aligned. Above T_c the moments have short-range order but not long-range order. Short-range order means there is local ordering. If a moment points in one direction, its neighbours have a tendency to point in the same direction. This tendency is maintained over several lattice sites but is not maintained for long distances. Long-range order is the tendency for moments to align for large distances. For temperatures a few degrees below T_c the moments have strong short-range order but only a small amount of long-range order, so the bar is not very magnetic. The tendency for long-range order increases at lower temperature. The Curie temperature is the point where long-range order begins as the temperature is lowered. The magnetization of nickel as a function of temperature is shown in Figure 16.

If an iron bar is heated to a temperature above T_c the bar is no longer magnetic. If the bar is then cooled to a temperature below T_c the grains become magnetic, but they orient their moments in random directions, so the bar as a whole is not magnetic. A bar can be demagnetized by heating the bar and then cooling it. By inserting it in a large magnetic field, the bar can be remagnetized.

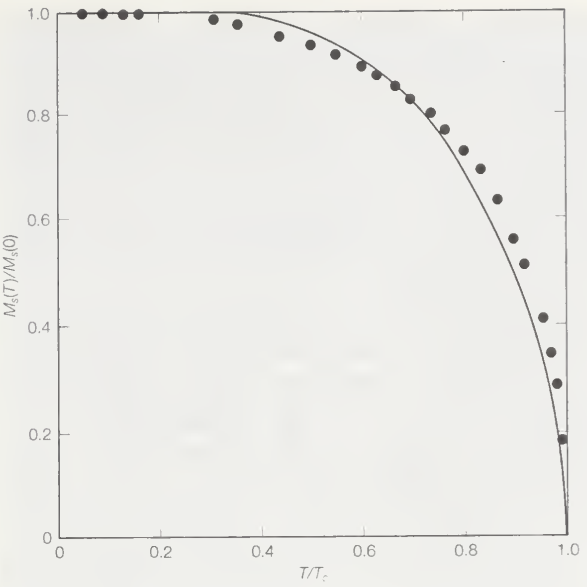

Figure 16: The total magnetization in nickel as a function of temperature. There is no long-range order above the Curie temperature T_c. $M_S(T)$ is the magnetization at temperature T, and $M_S(0)$ is the magnetization at absolute zero.

From P. Weiss and R. Forrer, *Annalen der Physik*, 5,153 (1926) in C. Kittel, *Introduction to Solid State Physics*, 4th ed., copyright © 1971 John Wiley & Sons, Inc.; reprinted by permission of John Wiley & Sons, Inc.

Ferromagnetism is found in many insulators as well as metals. Chromium bromide ($CrBr_3$) is an insulator since chromium is trivalent and a bromine atom needs one electron to complete its outer shell. The trivalent chromium atoms each have a moment, and these align ferromagnetically below the Curie temperature of 37 K. Gadolinium chloride ($GdCl_3$; $T_c = 2.2$ K) and europium oxide (EuO; $T_c = 77$ K) are two other examples among many.

Antiferromagnetic materials

Many crystals have magnetic ions that are ordered in arrangements other than ferromagnetic. In antiferromagnetic ordering, the moments pointing in one direction are balanced by others pointing in the opposite direction, with the result that the substance has no net magnetization. The exchange interaction between ions in this case has the opposite sign and favours the alternate arrangements of spins. The sign of the exchange interaction between ions depends on the length of the covalent bond and the bonding angles; it may have either orientation. The characteristic temperature associated with antiferromagnetism is called the Néel temperature T_N. Below T_N the ions are antiferromagnetically ordered, while above this temperature there is no long-range antiparallel order. Some examples of antiferromagnetic crystals are manganese oxide (MnO; $T_N = 116$ K), manganese sulfide (MnS; $T_N = 160$ K), and iron oxide (FeO; $T_N = 198$ K). Manganese oxide is an insulator since manganese atoms are divalent and oxygen atoms accept two electrons. The manganese ion has a fixed magnetic moment. The crystal structure of manganese oxide is the same as that of sodium chloride shown in Figure 7B. Below the Néel temperature the atomic unit cell doubles in size to include two atoms of each type of ion. This is necessary because below T_N neighbouring manganese atoms have moments in the opposite direction and are no longer equivalent; the unit cell must therefore include one moment in each of the two directions. Fluorides such as manganese fluoride (MnF_2), iron (II) fluoride (FeF_2), cobalt fluoride (CoF_2), and nickel fluoride (NiF_2) are other crystals that exhibit antiferromagnetic ordering of the transition metal ions.

Ferrimagnetism is another type of magnetic ordering. In ferrimagnets the moments are in an antiparallel alignment, but they do not cancel. The best example of a ferrimagnetic mineral is magnetite (Fe_3O_4). Two iron ions

are trivalent, while one is divalent. The two trivalent ions align with opposite moments and cancel one another, so the net moment arises from the divalent iron ion. The historic lodestone that was the first magnetic material discovered was a form of magnetite. Another class of ferrimagnets has the garnet structure; $Y_3Fe_5O_{12}$ is one such crystal. Only the iron ions are magnetic. Three point in one direction and two in the other, so there is a net magnetic moment of one iron ion in the unit cell. However, if a rare-earth ion such as gadolinium (Gd) is substituted for yttrium (Y), then the rare-earth ion also contributes to the ferrimagnetism.

Ferrites

Ferrites are oxides of iron with the formula MFe_2O_4, where M is a divalent ion such as nickel, zinc, cadmium, manganese, or magnesium. The ferric iron ion is trivalent, and the oxygen ion accepts two electrons. Actually M can also be divalent iron, forming magnetite (Fe_3O_4). The crystal structure is called spinel, which is the mineral name for $MgAl_2O_4$. Ferrites are electrical insulators with magnetic ordering. Their insulating quality makes them useful as magnetic cores. When metallic ferromagnetic materials are exposed to alternating magnetic fields, significant heating losses occur from eddy currents. Ferrite magnets greatly reduce such heat losses because of their high resistivity. They also absorb electromagnetic radiation of very long wavelengths. This property is unusual, since metals reflect such radiation while insulators transmit it. In small crystallites of ferrites, the electromagnetic radiation causes the magnetic moment to rotate at the frequency of light. The absorption frequency of the light depends on the detailed shape of the crystal grain. A polycrystalline material, with a range of grain sizes and shapes, absorbs over a broad range of radar frequencies. Ferrite crystals are a major ingredient in snooper paint, which makes stealth airplanes undetectable by radar. Regular airplanes reflect radar, and the reflected signals can be used to locate the aircraft. Stealth planes absorb the radar signals and so cannot be located in this way.

Magnetic ions have interesting properties when they are found as impurities in nonmagnetic crystals. They usually retain their magnetic moment, so small magnets are distributed randomly throughout the crystal. If the host crystal is a metal, the magnetic impurities make an interesting contribution to the electrical resistivity. The conduction electrons scatter from the magnetic impurity. Since the conduction electron and the impurity both have spin, they can mutually flip spins while scattering. The spin-flip scattering is strong at low temperatures and actually increases slightly as temperature decreases. This phenomenon is called the Kondo effect after the Japanese theoretical physicist Jun Kondo, who first explained the increase in resistivity resulting from magnetic impurities. There is a characteristic temperature, called the Kondo temperature, which depends on the impurity and on the metallic host. The resistivity increases at low temperature, starting near the Kondo temperature. A typical example of a Kondo system is iron impurities in copper; the system's Kondo temperature is 24 K. The solid line in Figure 17 shows the resistivity in copper at low temperature when there are 110 iron impurities per 1,000,000 copper atoms. The dashed line *a* is the resistivity in the absence of impurities. It increases at higher temperature because the electron scatters from ion vibrations. The dashed line *b* is the resistivity from spin-flip scattering. Nearly all transition metal atoms are found as magnetic impurities in copper or gold. Each system has a different Kondo temperature, which varies from 1,000 K to a fraction of 1 K. The spin-flip part of the electrical resistivity is unique in that it is large at low temperatures and decreases at high temperatures; most contributions to the resistivity increase at high temperatures. (G.D.Ma.)

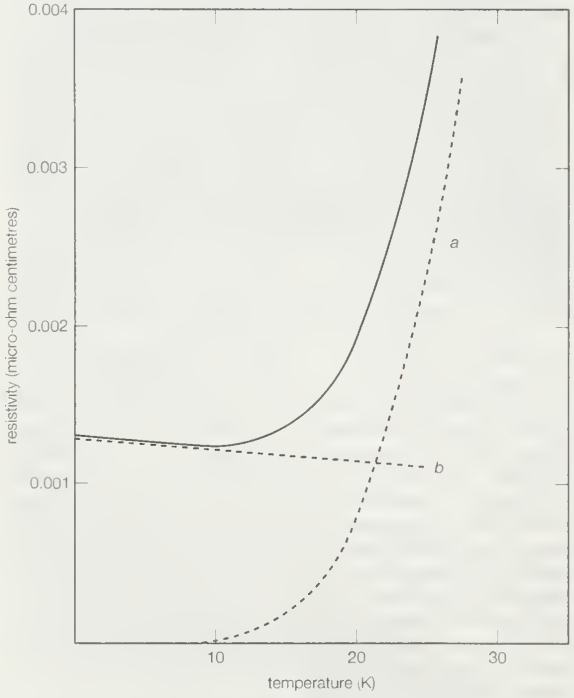

Figure 17: The electrical resistivity (solid line) of copper at low temperature when there are 110 iron atoms per 1,000,000 copper atoms. Without impurities the resistivity curve would be *a*. Curve *b* is the resistivity from the spin-flip scattering that results from the iron impurities.

Quasicrystals

Quasicrystals are metal alloys whose novel symmetries challenge the traditional dogma of crystallography. Although they appear at casual inspection to be ordinary crystals, they are not. Their symmetries elude the classification scheme of crystal structures, which enumerates the combinations of translational and rotational symmetries that are allowed according to the laws of crystallography. While ordinary crystals place atoms in periodic lattices, quasicrystals arrange atoms in a quasiperiodic fashion. Although these structures surprised the scientific community, it now appears that quasicrystals rank among the most common structures in alloys of aluminum with such metals as iron, cobalt, or nickel. While no major commercial applications yet exploit properties of the quasicrystalline state directly, quasicrystals form in compounds noted for their high strength and light weight, suggesting potential applications in aerospace and other industries.

STRUCTURE AND SYMMETRY

Dan Shechtman, a researcher from Technion, a part of the Israel Institute of Technology, and his colleagues at the National Bureau of Standards (now the National Institute of Standards and Technology) in Gaithersburg, Md., discovered quasicrystals in 1984. A research program of the U.S. Air Force sponsored their investigation of the metallurgical properties of aluminum-iron and aluminum-manganese alloys. Shechtman and his coworkers mixed aluminum and manganese in a roughly six-to-one proportion and heated the mixture until it melted. The mixture was then rapidly cooled back into the solid state by dropping the liquid onto a cold spinning wheel, a process known as melt spinning. When the solidified alloy was examined using an electron microscope, a novel structure was revealed. It exhibited fivefold symmetry, which is forbidden in crystals, and long-range order, which is lacking in amorphous solids. Its order, therefore, was neither amorphous nor crystalline. Many other alloys with these same features have subsequently been produced.

Discovery of quasicrystals

The electron microscope has played a significant role in the investigation of quasicrystals. It is a versatile tool that can probe many important aspects of the structure of matter. Low-resolution scanning electron microscopy magnifies the shapes of individual grains. Grains of a quasicrystalline aluminum-copper-iron alloy imaged with this technique are shown in Figure 18. Symmetries of solid grains often reflect the internal symmetries of the underlying atomic positions. Grains of salt, for example, take cubical shapes consistent with the cubic symmetries

of their crystal lattices. The shape observed in Figure 18 is called a pentagonal dodecahedron. Its 12 faces are regular pentagons, with axes of fivefold rotational symmetry passing through them. That is to say, rotations about this axis by 72° leave the appearance of the grain unchanged. In a full 360° rotation the grain will repeat itself in appearance five times, once every 72°. There are also axes of twofold rotational symmetry passing through the edges and axes of threefold rotational symmetry passing through the vertices. This is also known as icosahedral symmetry because the icosahedron is the geometric dual of the pentagonal dodecahedron. At the centre of each face on an icosahedron, the dodecahedron places a vertex, and vice versa. The symmetry of a pentagonal dodecahedron or icosahedron is not among the symmetries of any crystal structure, yet this is the symmetry that was revealed in the electron microscope image of the aluminum-manganese alloy produced by Shechtman and his colleagues.

High-resolution electron microscopy magnifies to such a great degree that patterns of atomic positions may be determined. In ordinary crystals such a lattice image reveals regularly spaced rows of atoms. Regular spacing implies spatial periodicity in the placement of atoms. The angles between rows indicate rotational symmetries of the atomic positions. A high-resolution electron microscope image of quasicrystalline aluminum-manganese-silicon is shown in Figure 19. Rows of atoms may be visualized by glancing along the page. Parallel rows occur in five sets, rotated from one another by 72°, confirming that the fivefold symmetry suggested by the shape of the pentagonal dodecahedron grain reflects a fivefold symmetry in the actual placement of atoms.

Translational periodicity

Fivefold symmetry axes are forbidden in ordinary crystals, while other axes, such as sixfold axes, are allowed. The reason is that translational periodicity, which is characteristic of crystal lattices, cannot be present in structures with fivefold symmetry. Figures 20 and 21 can be used to illustrate this concept. The triangular array of atoms in Figure 20 has axes of sixfold rotational symmetry passing through each atomic position. The arrows represent translational symmetries of this crystalline structure. That is, if the entire array of atoms is displaced along one of these arrows, say the one labeled *a*, all new atomic positions coincide with the locations of other atoms prior to the displacement. Such a displacement of atoms that leaves atomic positions invariant is called a symmetry of the crystal. In Figure 20, if two different symmetries are combined such that the structure is first displaced along arrow *a* and then along arrow *b*, the net result is equivalent to a displacement along arrow *c*, which itself must be a symmetry of the structure. Again, atomic sites coincide before

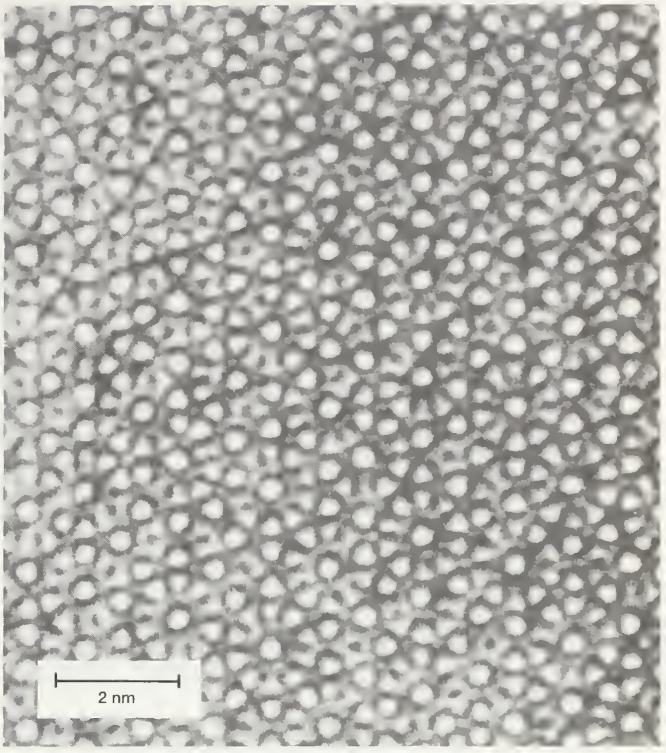

Figure 19: A high-resolution electron microscope image of quasicrystalline aluminum-manganese-silicon, revealing a fivefold symmetry of atomic positions. A glancing view along this figure reveals a Fibonacci sequence of dark and light rows.
Courtesy, Kenji Hiraga

and after the displacement. Repeated displacements along the same arrow demonstrate the translational periodicity of the crystal.

The atomic arrangement shown in Figure 21 exhibits fivefold rotational symmetry but lacks the translational symmetries that must be present in a crystalline structure. The arrows (other than arrow *c*) represent displacements that leave the arrangement invariant. Assume they are the shortest such displacements. Now, as before, consider the combinations of two symmetries *a* and *b* with the net result *c*. The length of *c* is smaller than either *a* or *b* by a factor $\tau = (\sqrt{5} + 1)/2$, which is known as the golden mean. The new atomic position, outlined with a dotted line, does not coincide with a previous atomic position, indicating that the structure does not exhibit translational periodicity. Therefore, an array of atoms may not simultaneously display fivefold rotational symmetry and translational periodicity, for, if it did, there would be no lower limit to the spacing between atoms.

In fact, the compatibility of translational periodicity with sixfold rotational symmetry (as shown in Figure 20) is a remarkable accident, for translational periodicity is not possible with most rotational symmetries. The only

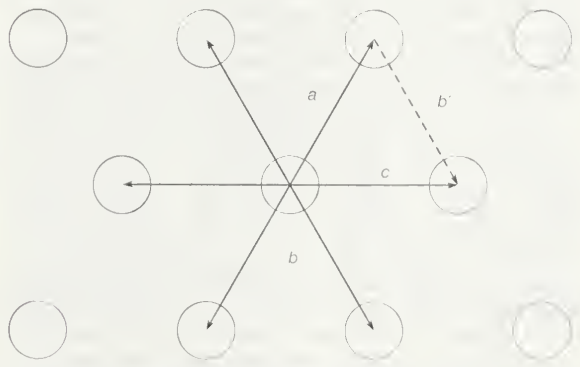

Figure 20: *Hexagonal lattice of atomic sites.* Arrows indicate translational symmetries of the lattice. Combining two symmetries (*a* and *b*) produces a third (*c*).

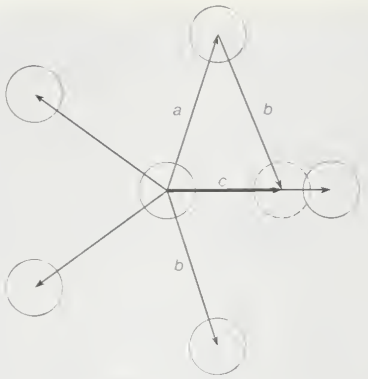

Figure 21: *Pentagonal arrangement of atoms.*
Arrows indicate hypothetical shortest translational symmetries. Combining two displacements produces a new displacement that is shorter than the hypothetical symmetries.

Symmetries found in quasicrystals

allowed symmetry axes in periodic crystals are twofold, threefold, fourfold, and sixfold. All others are forbidden owing to the lack of minimum interatomic separation. In particular, fivefold, eightfold, tenfold, and twelvefold axes cannot exist in crystals. These symmetries are mentioned in particular because they have been reported in quasicrystalline alloys.

Since the aluminum-manganese-silicon quasicrystal shown in Figure 19 clearly reveals an axis of fivefold symmetry, it may be concluded that the arrangement of atoms lacks translational periodicity. That, in itself, is no great surprise, for many materials lack translational periodicity. Amorphous metals, for example, are frequently produced by the same melt-spinning process that was employed in the discovery of quasicrystals. Amorphous metals have no discrete rotational symmetries, however, and high-resolution electron microscope images reveal no rows of atoms. The arrangement of atoms in a quasicrystal displays a property called long-range order, which is lacking in amorphous metals. Long-range order permits rows of atoms to span Figure 19 and maintains agreement of row orientations across the figure. Ordinary crystal structures, such as that of Figure 20, display long-range order. Strict rules govern the relative placement of atoms at remote locations in solids with long-range order.

Electron diffraction confirms the presence of long-range order in both crystals and quasicrystals. Quantum mechanics predicts that particles such as electrons move through space as if they were waves, in the same manner that light travels. When light waves strike a diffraction grating, they are diffracted. White light breaks up into a rainbow, while monochromatic light breaks up into discrete sharp spots. Similarly, when electrons strike evenly spaced rows of atoms within a crystalline solid, they break up into a set of bright spots known as Bragg diffraction peaks. Symmetrical arrangements of spots reveal axes of rotational symmetry in the crystal, and spacings between the discrete spots relate inversely to translational periodicities. Amorphous metals contain only diffuse rings in their diffraction patterns since long-range coherence in atomic positions is required to achieve sharp diffraction spots.

The original electron diffraction pattern of quasicrystalline aluminum-manganese published by Shechtman and his coworkers is shown in Figure 22. Rings of 10 bright spots indicate axes of fivefold symmetry, and rings of six bright spots indicate axes of threefold symmetry. The twofold symmetry axes are self-evident. The angles between these axes, indicated on the figure, agree with the geometry of the icosahedron. The very existence of spots at all indicates long-range order in atomic positions. Recalling the earlier result that fivefold symmetry axes are forbidden in crystalline materials, a paradox is presented by quasicrystals. They have long-range order in their atomic positions, but they must lack spatial periodicity.

Dov Levine and Paul Steinhardt, physicists at the University of Pennsylvania, proposed a resolution of this apparent conflict. They suggested that the translational order of atoms in quasicrystalline alloys might be quasiperiodic rather than periodic. Quasiperiodic patterns share certain characteristics with periodic patterns. In particular, both are deterministic—that is, rules exist that specify the entire pattern. These rules create long-range order. Both periodic and quasiperiodic patterns have diffraction patterns consisting entirely of Bragg peaks. The difference between quasiperiodicity and periodicity is that a quasiperiodic pattern never repeats itself. There are no translational symmetries, and, consequently, there is no minimum spacing between Bragg peaks. Although the peaks are discrete, they fill the diffraction pattern densely.

Quasiperiodicity

The most well-known quasiperiodic pattern may be the Fibonacci sequence, discovered during the Middle Ages in the course of studies conducted on rabbit reproduction. Consider the following rules for birth and maturation of rabbits. Start with a single mature rabbit (denoted by the symbol L for large) and a baby rabbit (denoted by S for small). In each generation every L rabbit gives birth to a new S rabbit, while each preexisting S rabbit matures into an L rabbit. A table of rabbit sequences may be established as follows. Start with an L and an S side by side along a line. Replace the L with LS and the S with L to obtain LSL and repeat the procedure as shown in Table 1. The numbers of rabbits present after each generation are the Fibonacci numbers. The population grows exponentially over time, with the population of each generation approaching τ (the golden mean) multiplied by the population of the previous generation. The sequence of L and S symbols forms a quasiperiodic pattern. It has no subunit that repeats itself periodically. In contrast, a periodic sequence such as LSLLSLLSLLSLLSL . . . has a fundamental unit (LSL) that is precisely repeated at equal intervals. In crystallography such a repeated unit is called a unit cell. Quasiperiodic sequences have no unit cell of finite size. Any portion of the Fibonacci sequence is repeated in-

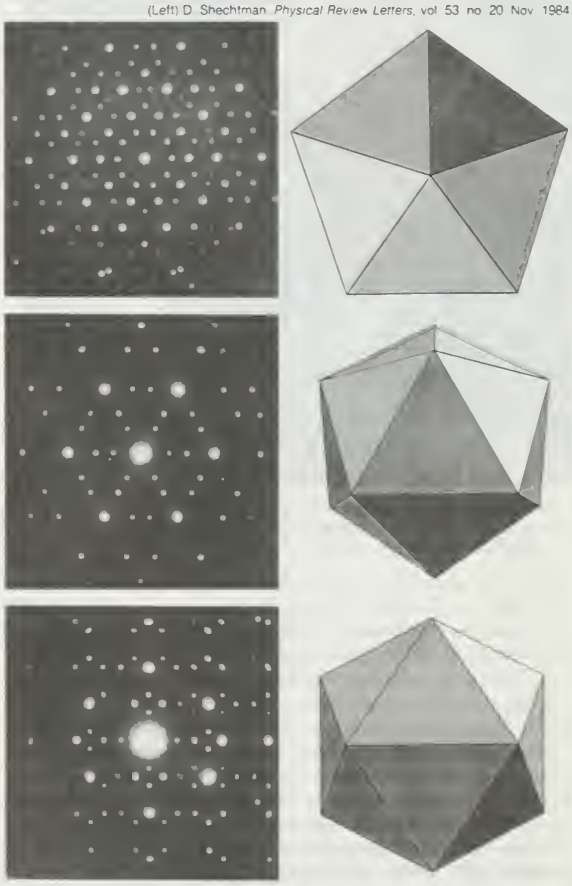

Figure 22: (Left) Electron diffraction patterns of quasicrystalline aluminum-manganese. (Top left) View is along the fivefold symmetry axis; (centre left) rotating by 37.38 reveals the threefold axis, and (bottom left) rotating by 58.29 reveals the twofold axis. (Right) Corresponding views of icosahedrons show that quasicrystalline symmetries match those of the icosahedrons.

Table 1: Fibonacci Sequences of Rabbits

generation	sequence	mature rabbits	babies
1	LS	1	1
2	LSL	2	1
3	LSLLS	3	2
4	LSLLSLSL	5	3
5	LSLLSLSLLSLLS	8	5
6	LSLLSLSLLSLLSLSLLSLSL	13	8

finitely often, but at intervals that are not periodic. These intervals themselves form a Fibonacci sequence.

The Penrose pattern

An example of a two-dimensional pattern that combines fivefold rotational symmetry with quasiperiodic translational order is the Penrose pattern, discovered by the English mathematical physicist Roger Penrose and shown in Figure 23. The diffraction pattern of such a sequence closely resembles the fivefold symmetric patterns of Figure 22. The rhombic tiles are arranged in sets of parallel rows; the shaded tiles represent one such set, or family. Five families of parallel rows are present in the figure, with 72° angles between the families, although only one of the five has been shaded. Within a family the spacings between rows are either large (L) or small (S), as labeled in the margin. The ratio of widths of the large rows to the small rows is equal to the golden mean τ, and the quasiperiodic sequence of large and small follows the Fibonacci sequence. An example of the use of Penrose tilings in an architectural application is shown in Figure 24.

Levine's and Steinhardt's proposal that quasicrystals possess quasiperiodic translational order can be examined in terms of the high-resolution electron micrograph in Figure 19. The rows of bright spots are separated by small and large intervals. As in the Penrose pattern, the length of the large interval divided by the length of the small one equals the golden mean, and the sequence of large and small reproduces the Fibonacci sequence. Levine's and Steinhardt's proposal appears consistent with the electron diffraction results. The origin of the name quasicrystals arises from the fact that these materials have quasiperiodic translational order, as opposed to the periodic order of ordinary crystals.

Symmetries observed in quasicrystals

Figures 18, 19, and 22 represent quasicrystals with the symmetry of an icosahedron. Icosahedral quasicrystals occur in many intermetallic compounds, including aluminum-copper-iron, aluminum-manganese-palladium, aluminum-magnesium-zinc, and aluminum-copper-lithium. Other crystallographically forbidden symmetries have been observed as well. These include decagonal symmetry, which exhibits tenfold rotational symmetry within two-dimensional atomic layers but ordinary translational periodicity perpendicular to these layers. Decagonal symmetry has been found in the compounds aluminum-copper-cobalt and aluminum-nickel-cobalt. Structures that are periodic in two dimensions but follow a Fibonacci sequence in the remaining third dimension occur in aluminum-copper-nickel.

All the compounds named thus far contain aluminum. Indeed, it appears that aluminum is unusually prone to quasicrystal formation, but there do exist icosahedral quasicrystals without it. Some, like gallium-magnesium-zinc, simply substitute the chemically similar element gallium for aluminum. Others, like titanium-manganese, appear chemically unrelated to aluminum-based compounds. Furthermore, some quasicrystals such as chromium-nickel-silicon and vanadium-nickel-silicon display octagonal and dodecagonal structures with eightfold or twelvefold symmetry, respectively, within layers and translational periodicity perpendicular to the layers.

The origin of quasicrystalline order remains in question. No proven explanation clarifies why a material favours crystallographically forbidden rotational symmetry and translational quasiperiodicity when at nearby compositions it forms more conventional crystal structures. The American chemist Linus Pauling noted that these related crystalline structures frequently contain icosahedral motifs within their unit cells, which are then repeated periodically. Pauling proposed that quasicrystals are really ordinary crystalline materials caught out of equilibrium by a type of crystal defect called twinning, in which unit cells are attached at angles defined by these icosahedral motifs. While this may be a reasonable model for rapidly cooled alloys such as Shechtman's original aluminum-manganese, other compounds, such as aluminum-copper-iron, possess quasicrystalline structures in thermodynamic equilibrium. These quasicrystals can be grown slowly and carefully using techniques for growth of high-quality conventional crystals. The more slowly the quasicrystal grows, the more perfect will be its rotational symmetry and quasiperiodicity. Measuring the sharpness of diffraction pattern spots shows perfect ordering on length scales of at least 30,000 angstroms in these carefully prepared quasicrystals. Twinning cannot account for such long-range order.

Levine and Steinhardt proposed that matching rules, such as those Penrose discovered to determine proper placement of his tiles to fill the plane quasiperiodically, may force the atoms into predefined, low-energy locations. Such a mechanism cannot be the complete explanation, though, since the compound forms ordinary crystalline structures at nearby compositions and temperatures. Indeed, it appears that, when quasicrystals are thermodynamically stable phases, it is only over a limited range of temperatures close to the melting point. At lower temperatures they transform into ordinary crystal structures. Thermodynamics predicts that the stable structure is the one that minimizes the free energy, defined as the ordinary energy minus the product of the temperature and the entropy. It is likely that entropy (a measure of fluctuations around an ideal structure) must be considered in addition to energy to explain stability of quasicrystals.

PROPERTIES

Along with their novel structures and symmetries, quasicrystals are expected to exhibit unusual properties. Both their elastic and their electronic behaviour distinguish quasicrystals from ordinary crystalline metals. Elastic response may be studied by measuring the speed of sound waves propagating through the metal. Sound speeds usually vary depending on the direction of propagation relative to axes of high rotational symmetry. Because the icosahedron has such high symmetry—it is closer to a sphere than is, for instance, a cube—the sound speeds turn out to be independent of the direction of propagation. Longitudinal sound waves (with displacements parallel to the direction of propagation) have speeds different from transverse waves (with displacements perpendicular to the direction of propagation), as is the case for all matter. Because the sound speeds do not depend on direction of propagation, only two elastic constants are required to specify acoustic properties of icosahedral quasicrystals. In contrast, cubic crystals require three elastic constants, and lower-symmetry crystals require up to 21 constants.

Elastic properties

As a consequence of the translational quasiperiodicity, there exists a second type of elastic deformation beyond the ordinary sound wave, or phonon. Known as phasons,

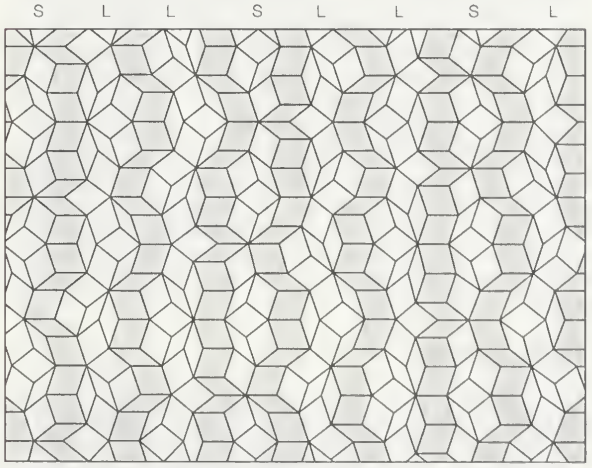

Figure 23: *A Penrose tiling.*
The plane is covered by rhombuses (deformed squares). Tiles with parallel edges lie in rows (shaded) separated by large (L) and small (S) intervals.

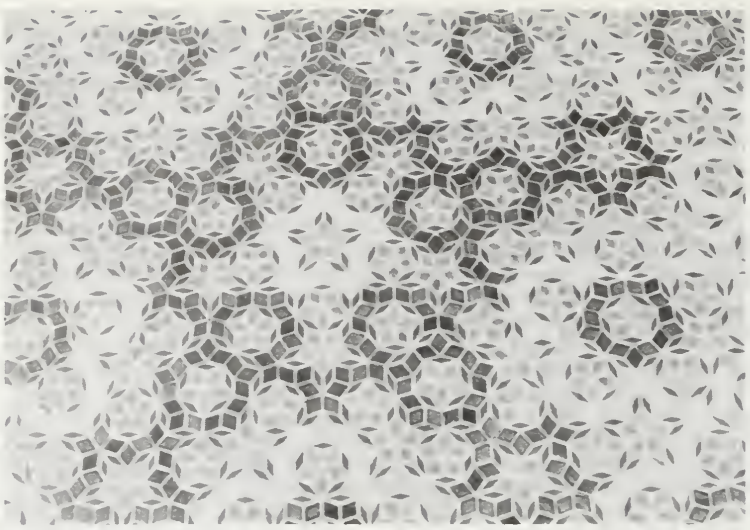

Figure 24: *Penrose tiles.*
Penrose tilings are used in architectural applications, as in these ceramic tiles coloured to emphasize the five-pointed stars and bands.
By courtesy of Saxe-Patterson Ceramics for Architecture

these elastic deformations correspond to rearrangements of the relative atomic positions. Removal of a phason requires adjusting positions of all atoms within a row of atoms in a quasicrystalline structure. At low temperatures motion of atoms within the solid is difficult, and phason strain may be easily frozen into the quasicrystal, limiting its perfection. At high temperatures, close to the melting point, phasons continually fluctuate, and atoms jump from place to place.

Electric properties

The electric properties of quasicrystals have proved to be rather unusual. Unlike their constituent elements, which tend to be good electrical conductors, quasicrystals conduct electricity poorly. For alloys of aluminum-copper-ruthenium these conductivities differ by as much as a factor of 100. As the perfection of the quasicrystalline order grows, the conductivity drops. Such behaviour is consistent with the appearance of a gap in the electronic density of states at the Fermi surface, which is the energy level separating filled electronic states from empty ones. Since it is only Fermi-surface electrons that carry current, a vanishingly small density of such electronic states leads to low electrical conductivities in semiconductors and insulators. Such a gap in the density of states may also play a role in explaining the formation of quasicrystalline structures. This is known as the Hume-Rothery rule for alloy formation. Since the Fermi-surface electrons are the highest-energy electrons, diminishing the number of such electrons may lower the overall energy.

The mechanical properties of quasicrystals are especially significant because the desire to develop a material that exhibited these properties motivated the investigators who discovered quasicrystals. Mechanical properties also relate to their first potential practical applications. Quasicrystals are exceptionally brittle. They have few dislocations, and those present have low mobility. Since metals bend by creating and moving dislocations, the near absence of dislocation motion causes brittleness. On the positive side, the difficulty of moving dislocations makes quasicrystals extremely hard. They strongly resist deformation. This makes them excellent candidates for high-strength surface coatings. Indeed, the first successful application of quasicrystals was as a surface treatment for aluminum frying pans.

Liquid crystals

Liquid crystals, their very name an oxymoron, blend structures and properties of the normally disparate liquid and crystalline solid states. Liquids can flow, for example, while solids cannot, and crystalline solids possess special symmetry properties that liquids lack. Ordinary solids melt into ordinary liquids as the temperature increases—*e.g.*, ice melts into liquid water. Some solids actually melt twice or more as temperature rises. Between the crystalline solid at low temperatures and the ordinary liquid state at high temperatures lies an intermediate state, the liquid crystal. Liquid crystals share with liquids the ability to flow but also display symmetries inherited from crystalline solids. The resulting combination of liquid and solid properties allows important applications of liquid crystals in the displays of such devices as wristwatches, calculators, portable computers, and flat-screen televisions.

STRUCTURE AND SYMMETRY

Crystals exhibit special symmetries when they slide in certain directions or rotate through certain angles. These symmetries can be compared to those encountered when walking in a straight line through empty space. Regardless of the direction or distance of each step, the view remains the same, as there are no landmarks by which to measure one's progress. This is called continuous translational symmetry because all positions look identical. Figure 25A illustrates a crystal in two dimensions. Such a crystal lat-

Translational symmetry

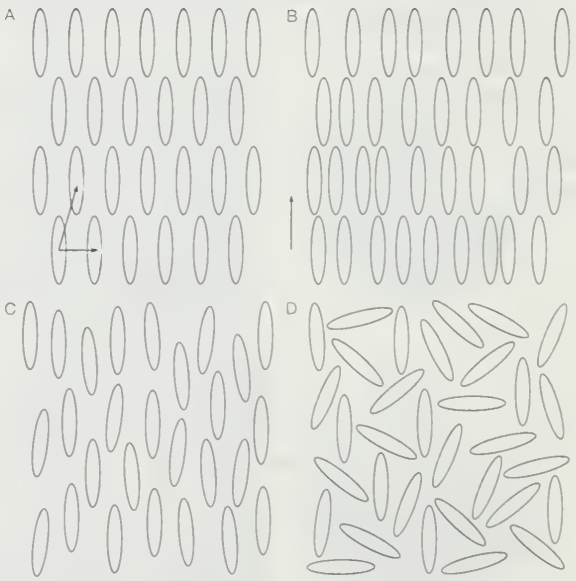

Figure 25: *Arrangements of molecules.*
(A) Ordinary crystals break the continuous rotational and translational symmetry of free space; discrete symmetries remain. (B) Smectic liquid crystals show broken translational symmetry in only one direction. (C) Nematic liquid crystals break only rotational symmetry. (D) Isotropic liquids share the continuous translational and rotational symmetry of free space. This symmetry may not be apparent in a single snapshot of molecular positions and orientations

tice breaks the continuous translational symmetry of free space; starting at one molecule there is a finite distance to travel before reaching the next. Some translational symmetry is present, however, because, by moving the proper distance in the proper direction, one is guaranteed to locate additional molecules on repeated excursions. This property is called discrete translational periodicity. The two-dimensional picture of a crystal displays translational periodicity in two independent directions. Real, three-dimensional crystals display translational periodicity in three independent directions.

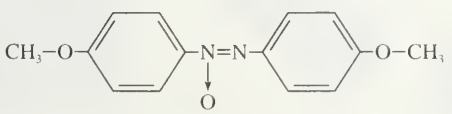
Rotational symmetries can be considered in a similar fashion. From one point in empty space, the view is the same regardless of which direction one looks. There is continuous rotational symmetry—namely, the symmetry of a perfect sphere. In the crystal shown in Figure 25A, however, the distance to the nearest molecule from any given molecule depends on the direction taken. Furthermore, the molecules themselves may have shapes that are less symmetric than a sphere. A crystal possesses a certain discrete set of angles of rotation that leave the appearance unchanged. The continuous rotational symmetry of empty space is broken, and only a discrete symmetry exists. Broken rotational symmetry influences many important properties of crystals. Their resistance to compression, for example, may vary according to the direction along which one squeezes the crystal. Transparent crystals, such as quartz, may exhibit an optical property known as birefringence. When a light ray passes through a birefringent crystal, it is bent, or refracted, at an angle depending on the direction of the light and also its polarization, so that the single ray is broken up into two polarized rays. This is why one sees a double image when looking through such crystals.

In a liquid such as the one shown in Figure 25D, all the molecules sit in random positions with random orientations. This does not mean that there is less symmetry than in the crystal, however. All positions are actually equivalent to one another, and likewise all orientations are equivalent, because in a liquid the molecules are in constant motion. At one instant the molecules in the liquid may occupy the positions and orientations shown in Figure 25D, but a moment later the molecules will move to previously empty points in space. Likewise, at one instant a molecule points in one direction, and the next instant it points in another. Liquids share the homogeneity and isotropy of empty space; they have continuous translational and rotational symmetries. No form of matter has greater symmetry.

Symmetry of liquids

As a general rule, molecules solidify into crystal lattices with low symmetry at low temperatures. Both translational and rotational symmetries are discrete. At high temperatures, after melting, liquids have high symmetry. Translational and rotational symmetries are continuous. High temperatures provide molecules with the energy needed for motion. The mobility disorders the crystal and raises its symmetry. Low temperatures limit motion and the possible molecular arrangements. As a result, molecules remain relatively immobile in low-energy, low-symmetry configurations.

Liquid crystals, sometimes called mesophases, occupy the middle ground between crystalline solids and ordinary liquids with regard to symmetry, energy, and properties. Not all molecules have liquid crystal phases. Water molecules, for example, melt directly from solid crystalline ice into liquid water. The most widely studied liquid-crystal-forming molecules are elongated, rodlike molecules, rather like grains of rice in shape (but far smaller in size). A popular example is the molecule *p*-azoxyanisole (PAA):



Liquid crystal structures

Typical liquid crystal structures include the smectic shown in Figure 25B and the nematic in Figure 25C (this nomenclature, invented in the 1920s by the French scientist Georges Friedel, will be explained below). The smectic phase differs from the solid phase in that translational symmetry is discrete in one direction—the vertical in Figure 25B—and continuous in the remaining two. The continuous translational symmetry is horizontal in the figure, because molecule positions are disordered and mobile in this direction. The remaining direction with continuous translational symmetry is not visible, because this figure is only two-dimensional. To envision its three-dimensional structure, imagine the figure extending out of the page.

In the nematic phase all translational symmetries are continuous. The molecule positions are disordered in all directions. Their orientations are all alike, however, so that the rotational symmetry remains discrete. The orientation of the long axis of a nematic molecule is called its director. In Figure 25C the nematic director is vertical.

It was noted above that, as temperature decreases, matter tends to evolve from highly disordered states with continuous symmetries toward ordered states with discrete symmetries. This can occur through a sequence of symmetry-breaking phase transitions. As a substance in the liquid state is reduced in temperature, rotational symmetry breaking creates the nematic liquid crystal state in which molecules are aligned along a common axis. Their directors are all nearly parallel. At lower temperatures continuous translational symmetries break into discrete symmetries. There are three independent directions for translational symmetry. When continuous translational symmetry is broken along only one direction, the smectic liquid crystal is obtained. At temperatures sufficiently low to break continuous translational symmetry in all directions, the ordinary crystal is formed.

The mechanism by which liquid crystalline order is favoured can be illustrated through an analogy between molecules and grains of rice. Collisions of molecules require energy, so the greater the energy, the greater the tolerance for collisions. If rice grains are poured into a pan, they fall at random positions and orientations and tend to jam up against their neighbours. This is similar to the liquid state illustrated in Figure 25D. After the pan is shaken to allow the rice grains to readjust their positions, the neighbouring grains tend to line up. The alignment is not perfect across the sample owing to defects, which also can occur in nematic liquid crystals. When all grains align, they have greater freedom to move before hitting a neighbour than they have when they are disordered. This produces the nematic phase, illustrated in Figure 25C. The freedom to move is primarily in the direction of molecular alignment, as sideways motion quickly results in collision with a neighbour. Layering the grains, as illustrated in Figure 25B, enhances sideways motion. This produces the smectic phase. In the smectic phase some molecules have ample free volume to move in, while others are tightly packed. The lowest-energy arrangement shares the free volume equitably among molecules. Each molecular environment matches all others, and the structure is a crystal like that illustrated in Figure 25A.

Rice-grain analogy

There is a great variety of liquid crystalline structures known in addition to those described so far. Table 2 relates some of the chief structures according to their degree and type of order. The smectic-C phase and those listed below it have molecules tilted with respect to the layers. Continuous in-plane rotational symmetry, present within smectic-A layers, is broken in the hexatic-B phase, but a proliferation of dislocations maintains continuous translational symmetry within its layers. A similar relationship holds between smectic-C and smectic-F. Crystal-B and crystal-G have molecular positions on regular crystal lattice sites, with long axes of molecules (directors) aligned, but allow rotation of molecules about their directors. These are the so-called plastic crystals. Many interesting liquid crystal phases are not listed in this table, including the discotic phase, consisting of disk-shaped molecules, and the columnar phases, in which translational symmetry is broken in not one but two spatial directions, leaving liquidlike order only along columns. The degree of order increases from the top to the bottom of the table. In general, phases from the top of the table are expected at high temperatures, and phases from the bottom at low temperatures.

Table 2: Selected Phases Characteristic of Liquid-Crystal-Forming Molecules

phase		order
Isotropic liquid		full continuous translational and rotational symmetry
Nematic		molecular orientation breaks rotational symmetry
untilted	tilted	
Smectic-A	Smectic-C	layering breaks translational symmetry; smectic-C molecules are tilted
Hexatic-B	Smectic-F	bond orientational order breaks rotational symmetry within layers
Crystal-B	Crystal-G	crystallization breaks translational symmetry within layers; molecules may rotate about their long axis
Crystal-E	Crystal-H	molecular rotation freezes out

Structure of soap molecules

Liquid-crystal-forming compounds are widespread and quite diverse. Soap (see Figure 26) can form a type of smectic known as a lamellar phase, also called neat soap. In this case it is important to recognize that soap molecules have a dual chemical nature. One end of the molecule (the hydrocarbon tail) is attracted to oil, while the other end (the polar head) attaches itself to water. When soap is placed in water, the hydrocarbon tails cluster together, while the polar heads adjoin the water. Small numbers of soap molecules form spherical or rodlike micelles (Figure 26B), which float freely in the water, while concentrated solutions create bilayers (Figure 26C), which stack along some direction just like smectic layers. Indeed, the name smectic is derived from the Greek word for soap. The slippery feeling caused by soap reflects the ease with which the layers slide across one another.

Biologically important liquid crystals

Many biological materials form liquid crystals. Myelin, a fatty material extracted from nerve cells, was the first intensively studied liquid crystal. The tobacco mosaic virus, with its rodlike shape, forms a nematic phase. In cholesterol the nematic phase is modified to a cholesteric phase characterized by continuous rotation of the direction of molecular alignment. An intrinsic twist of the cholesterol molecule, rather like the twist of the threads of a screw, causes this rotation. Since the molecular orientation rotates steadily, there is a characteristic distance after which the orientation repeats itself. This distance is frequently comparable to the wavelength of visible light, so brilliant colour effects result from the diffraction of light by these materials.

Perhaps the first description of a liquid crystal occurred in the story *The Narrative of Arthur Gordon Pym*, by Edgar Allan Poe:

> I am at a loss to give a distinct idea of the nature of this liquid, and cannot do so without many words. Although it flowed with rapidity in all declivities where common water would do so, yet never, except when falling in a cascade, had it the customary appearance of *limpidity*. . . . At first sight, and especially in cases where little declivity was found, it bore resemblance, as regards consistency, to a thick infusion of gum Arabic in common water. But this was only the least remarkable of its extraordinary qualities. It was *not* colourless, nor was it of any one uniform colour—presenting to the eye, as it flowed, every possible shade of purple, like the hues of a changeable silk. . . . Upon collecting a basinful, and allowing it to settle thoroughly, we perceived that the whole mass of liquid was made up of a number of distinct veins, each of a distinct hue; that these veins did not commingle; and that their cohesion was perfect in regard to their own particles among themselves, and imperfect in regard to neighbouring veins. Upon passing the blade of a knife athwart the veins, the water closed over it immediately, as with us, and also, in withdrawing it, all traces of the passage of the knife were instantly obliterated. If, however, the blade was passed down accurately between two veins, a perfect separation was effected, which the power of cohesion did not immediately rectify.

The liquid described in this passage is human blood. In its usual state within the human body, blood is an ordinary disordered isotropic fluid. The disklike shape of red blood cells, however, favours liquid crystallinity at certain concentrations and temperatures.

OPTICAL PROPERTIES

An understanding of the principal technological applications of liquid crystals requires a knowledge of their optical properties. Liquid crystals alter the polarization of light passing through them. Light waves are actually waves in electric and magnetic fields. The direction of the electric field is the polarization of the light wave. A polarizing filter selects a single component of polarized light to pass through while absorbing all other components of incoming waves. If a second polarizing filter is placed above the first but with its polarization axis rotated by 90°, no light can pass through because the polarization passed by the first filter is precisely the polarization blocked by the second filter. When optically active materials, such as liquid crystals, are placed between polarizing filters crossed in this manner, some light may get through, because the intervening material changes the polarization of the light. If the nematic director is not aligned with either of the polarizing filters, polarized light passing through the first filter becomes partially polarized along the nematic director. This component of light in turn possesses a component aligned with the top polarizing filter, so a fraction of the incoming light passes through the entire assembly. The amount of light passing through is largest when the nematic director is positioned at a 45° angle from both filters. The light is fully blocked when the director lies parallel to one filter or the other.

During the last decades of the 19th century, pioneering

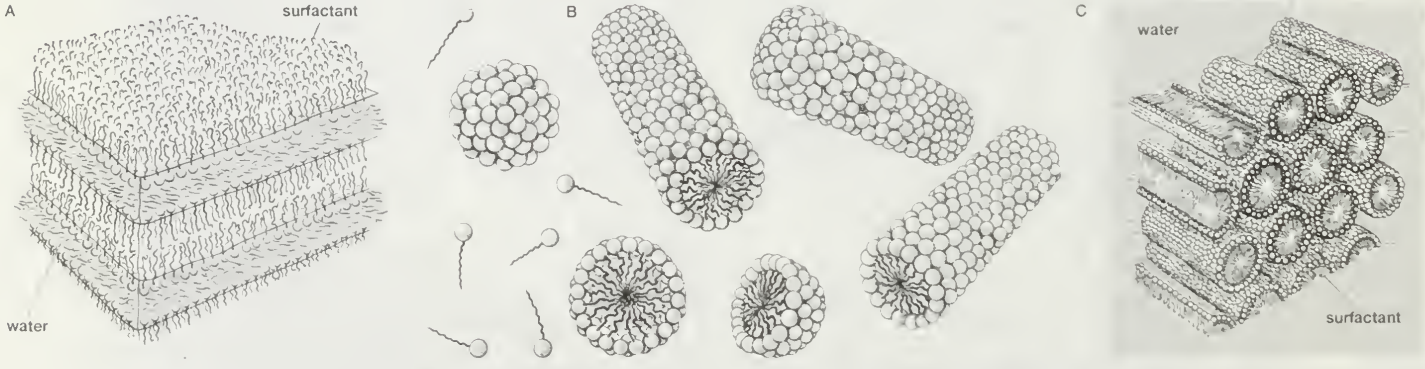


Figure 26: *Structures of soap in water.*

investigators of liquid crystals, such as the German physicist Otto Lehmann and the Austrian botanist Friedrich Reinitzer, equipped ordinary microscopes with pairs of polarizing filters. Typical microscope images of nematic and smectic phases taken through crossed polarizers are shown in Figure 27. Spatial variation in the alignment of the nematic director causes spatial variation in light intensity. Since the nematic is defined by having all directors nearly parallel to one another, the images arise from defects in the nematic structure. Figure 27 (bottom) illustrates a manner in which the directors may rotate or bend around defect lines. The resulting threadlike images inspired the name nematic, which is based on the Greek word for thread. The layered smectic structure causes layering of defects in Figure 27 (centre).

Nonuniformity in director alignment may be induced

Figure 27: (Top) Nematic and (centre) smectic liquid crystals viewed through microscopes equipped with crossed polarizers. (Bottom) Spatial variation of the director, causing the threadlike image seen in the photograph at top.

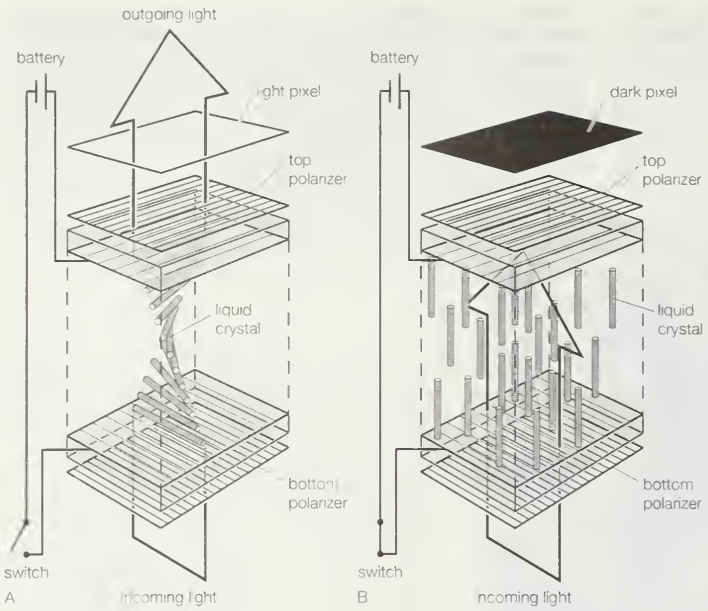

Figure 28: *A twisted-nematic cell.*
(A) The assembly is transparent to light in the absence of an electric field. (B) An applied field destroys the twist of the nematic, rendering the assembly opaque.

From J. Funfschilling, "Liquid Crystals and Liquid Crystal Displays" *Condensed Matter News*, vol. 1, no. 1, 1991 Gordon and Breach Science Publishers

artificially. The surfaces of a glass container can be coated with a material that, when rubbed in the proper direction, forces the director to lie perpendicular or parallel to the wall adjacent to a nematic liquid crystal. The orientation forced by one wall need not be consistent with that forced by another wall; this situation causes the director orientation to vary in between the walls. The nematic must compromise its preference for all directors to be parallel to one another with the inconsistent orienting forces of the container walls. In doing so, the liquid crystal may take on a twisted alignment across the container (see Figure 28A.) Electric or magnetic fields provide an alternate means of influencing the orientation of the nematic directors. Molecules may prefer to align so that their director is, say, parallel to an applied electric field.

The twisted-nematic cell

Optical behaviour and orienting fields underlie the important contemporary use of liquid crystals as opto-electronic displays. Consider, for example, the twisted-nematic cell shown in Figure 28A. The polarizer surfaces are coated and rubbed so that the nematic will align with the polarizing axis. The two polarizers are crossed, forcing the nematic to rotate between them. The rotation is slow and smooth, assuming a 90° twist across the cell. Light passing through the first polarizer is aligned with the bottom of the nematic layer. As the nematic twists, it rotates the polarization of the light so that, as the light leaves the top of the nematic layer, its polarization is rotated by 90° from that at the bottom. The new polarization is just right for passing through the top filter, and so light travels unhindered through the assembly.

If an electric field is applied in the direction of light propagation, the liquid crystal directors align with the orienting field, so they are no longer parallel to the light passing though the bottom polarizer (Figure 28B). They are no longer capable of rotating this polarization through the 90° needed to allow the light to emerge from the top polarizer. Although this assembly is transparent when no field is applied, it becomes opaque when the field is present. A grid of such assemblies placed side by side may be used to display images. If one turns on the electric field attached to the parts of the grid that lie where the image is to appear, these points will turn black while the remaining points of the grid stay white. The resulting patchwork of dark and light creates the image on the display. In a wristwatch, calculator, or computer these may be simply numbers or letters, and in a television the images may be detailed pictures. Switching the electric fields on or off will cause the picture to move, just as ordinary television pictures display an ever-changing stream of electrically encoded images. (M.W.)

Amorphous solids

Solids and liquids are both forms of condensed matter; both are composed of atoms in close proximity to each other. But their properties are, of course, enormously

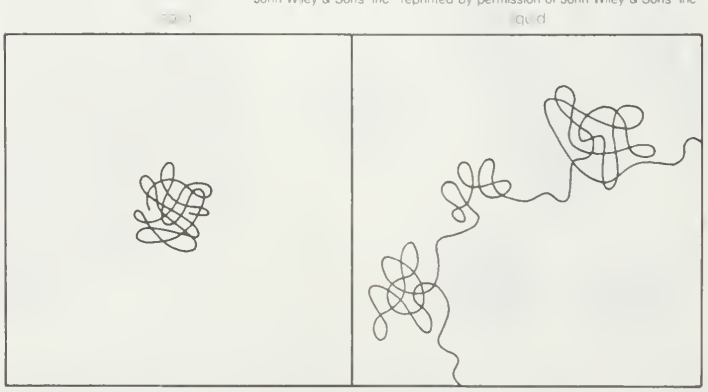

Figure 29: The state of atomic motion (left) in a solid and (right) in a liquid.

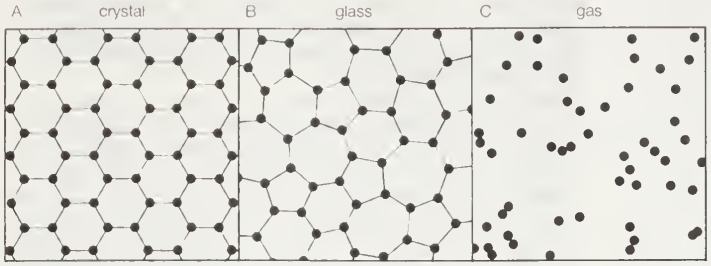

Figure 30: The atomic arrangements in (A) a crystalline solid, (B) an amorphous solid, and (C) a gas.

Defining characteristics of solids

different. While a solid material has both a well-defined volume and a well-defined shape, a liquid has a well-defined volume but a shape that depends on the shape of the container. Stated differently, a solid exhibits resistance to shear stress while a liquid does not. Externally applied forces can twist or bend or distort a solid's shape, but (provided the forces have not exceeded the solid's elastic limit) it "springs back" to its original shape when the forces are removed. A liquid flows under the action of an external force; it does not hold its shape. These macroscopic characteristics constitute the essential distinctions: a liquid flows, lacks a definite shape (though its volume is definite), and cannot withstand a shear stress; a solid does not flow, has a definite shape, and exhibits elastic stiffness against shear stress.

On an atomic level, these macroscopic distinctions arise from a basic difference in the nature of the atomic motion. Figure 29 contains schematic representations of atomic movements in a liquid and a solid. Atoms in a solid are not mobile. Each atom stays close to one point in space, although the atom is not stationary but instead oscillates rapidly about this fixed point (the higher the temperature, the faster it oscillates). The fixed point can be viewed as a time-averaged centre of gravity of the rapidly jiggling atom. The spatial arrangement of these fixed points constitutes the solid's durable atomic-scale structure. In contrast, a liquid possesses no enduring arrangement of atoms. Atoms in a liquid are mobile and continually wander throughout the material.

DISTINCTION BETWEEN CRYSTALLINE AND AMORPHOUS SOLIDS

There are two main classes of solids: crystalline and amorphous. What distinguishes them from one another is the nature of their atomic-scale structure. The essential differences are displayed in Figure 30. The salient features of the atomic arrangements in amorphous solids (also called glasses), as opposed to crystals, are illustrated in the figure for two-dimensional structures; the key points carry over to the actual three-dimensional structures of real materials. Also included in the figure, as a reference point, is a sketch of the atomic arrangement in a gas. For the sketches representing crystal (A) and glass (B) structures, the solid dots denote the fixed points about which the atoms oscillate; for the gas (C), the dots denote a snapshot of one configuration of instantaneous atomic positions.

Atomic positions in a crystal exhibit a property called long-range order or translational periodicity; positions repeat in space in a regular array, as in Figure 30A. In an amorphous solid, translational periodicity is absent. As indicated in Figure 30B, there is no long-range order. The atoms are not randomly distributed in space, however, as they are in the gas in Figure 30C. In the glass example illustrated in the figure, each atom has three nearest-neighbour atoms at the same distance (called the chemical bond length) from it, just as in the corresponding crystal. All solids, both crystalline and amorphous, exhibit short-range (atomic-scale) order. (Thus, the term amorphous, literally "without form or structure," is actually a misnomer in the context of the standard expression amorphous solid.) The well-defined short-range order is a consequence of the chemical bonding between atoms, which is responsible for holding the solid together.

Short-range order

In addition to the terms amorphous solid and glass, other terms in use include noncrystalline solid and vitreous solid. Amorphous solid and noncrystalline solid are more general terms, while glass and vitreous solid have historically been reserved for an amorphous solid prepared by rapid cooling (quenching) of a melt—as in scenario 2 of Figure 31.

Figure 31, which should be read from right to left, indicates the two types of scenarios that can occur when cooling causes a given number of atoms to condense from the gas phase into the liquid phase and then into the solid phase. Temperature is plotted horizontally, while the volume occupied by the material is plotted vertically. The temperature T_b is the boiling point, T_f is the freezing (or melting) point, and T_g is the glass transition temperature. In scenario 1 the liquid freezes at T_f into a crystalline solid, with an abrupt discontinuity in volume. When cooling occurs slowly, this is usually what happens. At sufficiently high cooling rates, however, most materials display a different behaviour and follow route 2 to the solid state. T_f is bypassed, and the liquid state persists until the lower temperature T_g is reached and the second solidification scenario is realized. In a narrow temperature range near T_g, the glass transition occurs: the liquid freezes into an amorphous solid with no abrupt discontinuity in volume.

The glass transition temperature T_g is not as sharply defined as T_f; T_g shifts downward slightly when the cooling rate is reduced. The reason for this phenomenon is the steep temperature dependence of the molecular response time, which is crudely indicated by the order-of-magnitude values shown along the top scale of Figure 31. When the temperature is lowered below T_g, the response time for molecular rearrangement becomes much larger than experimentally accessible times, so that liquidlike mobility (Figure 29, right) disappears and the atomic configuration becomes frozen into a set of fixed positions to which the atoms are tied (Figures 29, left, and 30B).

Some textbooks erroneously describe glasses as undercooled viscous liquids, but this is actually incorrect. Along the section of route 2 labeled liquid in Figure 31, it is the

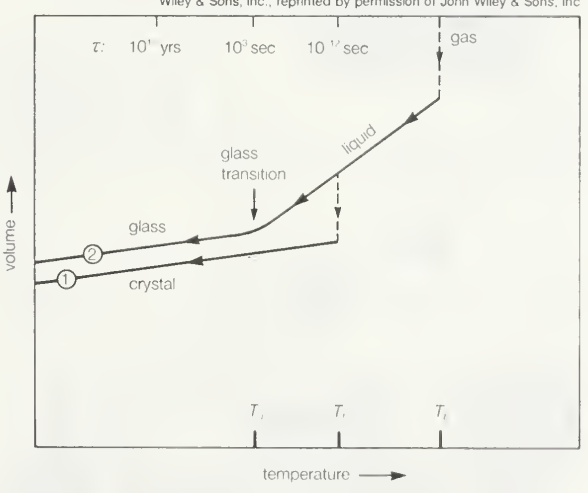

Figure 31: The two general cooling paths by which a group of atoms can condense. Route 1 is the path to the crystalline state; route 2 is the rapid-quench path to the amorphous solid state.

Table 3: Bonding Types and Glass Transition Temperatures of Representative Amorphous Solids

glass	bonding	T_g (K)
SiO_2	covalent	1,430
GeO_2	covalent	820
Si, Ge	covalent	—
$Pd_{0.4}Ni_{0.4}P_{0.2}$	metallic	580
BeF_2	ionic	570
As_2S_3	covalent	470
Polystyrene	polymeric	370
Se	polymeric	310
$Au_{0.8}Si_{0.2}$	metallic	290
H_2O	hydrogen-bonded	140
C_2H_5OH	hydrogen-bonded	90
Isopentane	van der Waals	65
Fe, Co, Bi	metallic	—

portion lying between T_f and T_g that is correctly associated with the description of the material as an undercooled liquid (undercooled meaning that its temperature is below T_f). But below T_g, in the glass phase, it is a bona fide solid (exhibiting such properties as elastic stiffness against shear). The low slopes of the crystal and glass line segments of Figure 31 in comparison with the high slope of the liquid section reflect the fact that the coefficient of thermal expansion of a solid is small in comparison with that of the liquid.

PREPARATION OF AMORPHOUS SOLIDS

It was once thought that relatively few materials could be prepared as amorphous solids, and such materials (notably, oxide glasses and organic polymers) were called glass-forming solids. It is now known that the amorphous solid state is almost a universal property of condensable matter. Table 3 presents a list of amorphous solids in which every class of chemical bonding type is represented. The glass transition temperatures span a wide range.

Glass formation is a matter of bypassing crystallization. The channel to the crystalline state is evaded by quickly crossing the temperature interval between T_f and T_g. Nearly all materials can, if cooled quickly enough, be prepared as amorphous solids. The definition of "quickly enough" varies enormously from material to material. Four techniques for preparing amorphous solids are illustrated in Figure 32. These techniques are not fundamentally different from those used for preparing crystalline solids; the key is simply to quench the sample quickly enough to form the glass, rather than slowly enough to form the crystal. The quench rate increases greatly from left to right in the figure.

Preparation of metallic glasses requires a quite rapid quench. The technique shown in Figure 32C, called splat quenching, can quench a droplet of a molten metal roughly 1,000° C in one millisecond, producing a thin film of metal that is an amorphous solid. In enormous contrast to this, the silicate glass that forms the rigid ribbed disk of the Hale telescope of the Palomar Observatory near San Diego, Calif., was prepared by cooling (over a comparable temperature drop) during a time interval of eight months. The great difference in the quench rates needed for arriving at the amorphous solid state (the quench rates here differ by a factor of 3×10^{10}) is a dramatic demonstration of the difference in the glass-forming tendency of silicate glasses (very high) and metallic glasses (very low).

Splat quenching

The required quench rate for glass formation can vary significantly within a family of related materials that differ from one another in chemical composition. Figure 33 illustrates a representative behaviour for a binary (two-component) system, gold-silicon. Here x specifies the fraction of atoms that are silicon atoms, and $Au_{1-x}Si_x$ denotes a particular material in this family of materials. (Au is the chemical symbol for gold, Si is the symbol for silicon, and, for example, $Au_{0.8}Si_{0.2}$ denotes a material containing 20 percent silicon atoms and 80 percent gold atoms.) The solid curve labeled T_f shows the composition dependence of the freezing point; above this line the liquid phase is the stable form. There is a deep cusp near the composition $x = 0.2$. Near this special composition, as at a in the figure, a liquid is much more readily quenched than is a liquid at a distant composition such as b. To reach the glass phase, the liquid must be cooled from above T_f to below T_g without crystallizing. Throughout the temperature interval from T_f down to the glass transition temperature T_g, the liquid is at risk vis-à-vis crystallization. Since this dangerous interval is much longer at b than at a, a faster quench rate is needed for glass formation at b than at a.

Diagrams similar to (though slightly more complicated than) Figure 33 exist for many binary systems. For example, in the oxide system CaO-Al_2O_3, in which the two end-member compositions ($x = 0$ and $x = 1$) correspond to pure calcium oxide (CaO) and pure aluminum oxide

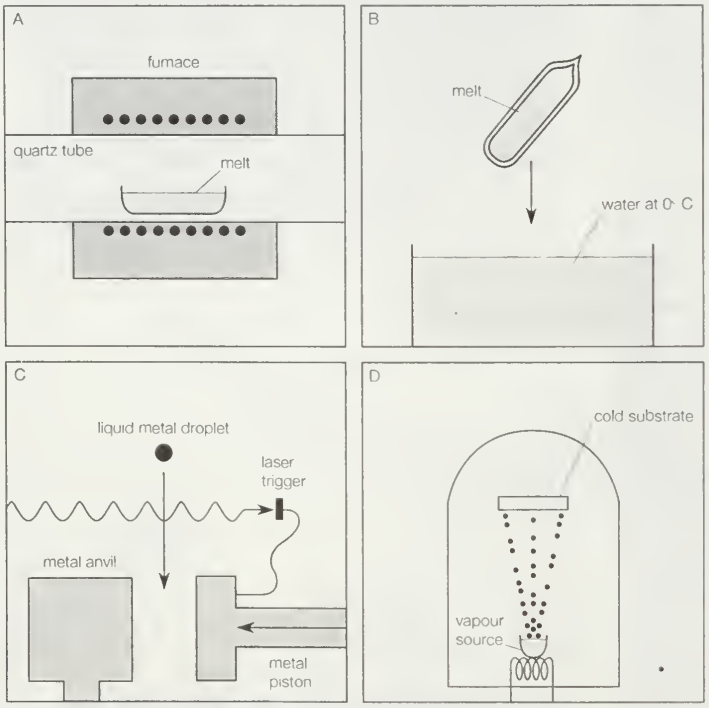

Figure 32: *Four methods for preparing amorphous solids.* (A) Slow cooling, (B) moderate quenching, (C) rapid splat quenching, and (D) condensation from the gas phase.

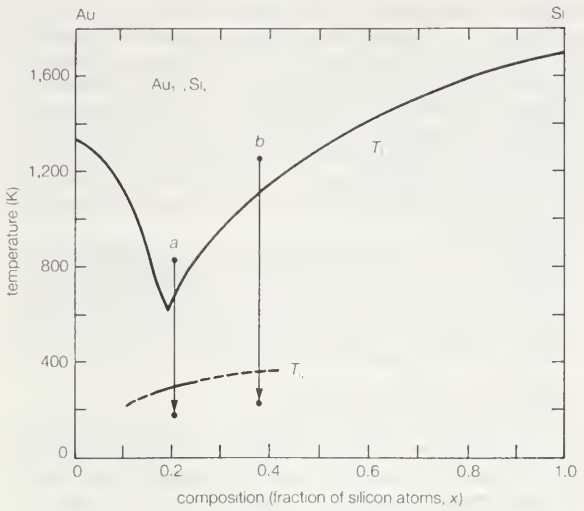

Figure 33: *Glass formation in the gold-silicon system.* Two quenches from the liquid state are shown. Glasses can be prepared more easily with quench *a* than with quench *b*, because the latter requires the liquid to cross a larger temperature interval between the freezing temperature T_l and the glass transition temperature T_g; this is the temperature region in which crystallization is prone to occur.

Based on R. Zallen, *The Physics of Amorphous Solids*, copyright © 1983 John Wiley & Sons, Inc., reprinted by permission of John Wiley & Sons, Inc.; T_l curve from B. Predel and H. Bankstahl, *Journal of the Less-Common Metals*, no. 43, 1975, Elsevier Sequoia, publisher; T_g curve from H.S. Chen and D. Turnbull, *The Journal of Chemical Physics*, no. 48, 1968, published by the American Institute of Physics

(Al_2O_3), there is a deep minimum in the T_l-versus-x curve near the middle of the composition range. Although neither calcium oxide nor aluminum oxide readily forms a glass, glasses are easily formed from mixed compositions; for reasons related to this, many oxide glasses have complex chemical compositions.

In the gold-silicon system of Figure 33, at compositions far from the cusp, glasses cannot be formed by melt quenching—even by the rapid splat-quench technique of Figure 32. (This is the reason that the T_g curve of Figure 33 spans only compositions near the cusp.) Amorphous solids can still be prepared by dispensing with the liquid phase completely and constructing a thin solid film in atom-by-atom fashion from the gas phase. Figure 32D shows the simplest of these vapour-condensation techniques. A vapour stream, formed within a vacuum chamber by thermal evaporation of a sample of the material to be deposited, impinges on the surface of a cold substrate. The atoms condense on the cold surface and, under a range of conditions (usually a high rate of deposition and a low substrate temperature), an amorphous solid is formed as a thin film. Pure silicon can be prepared as an amorphous solid in this manner. Variations of the method include using an electron beam to vapourize the source or using the plasma-induced decomposition of a molecular species. The latter technique is used to deposit amorphous silicon from gaseous silane (SiH_4). Among the amorphous solids listed in Table 3, those that normally require vapour-condensation methods for their preparation are silicon (Si), germanium (Ge), water (H_2O), and the elemental metallic glasses iron (Fe), cobalt (Co), and bismuth (Bi).

Vapour-condensation preparation

Numerous other methods exist for preparing amorphous solids, and new methods are continually invented. In melt spinning, a jet of molten metal is propelled against the moving surface of a cold, rotating copper cylinder. A solid film of metallic glass is spun off as a continuous ribbon at a speed that can exceed a kilometre per minute. In laser glazing, a brief intense laser pulse melts a tiny spot, which is swiftly quenched by the surrounding material into a glass. In sol-gel synthesis, small molecules in a liquid solution chemically link up with each other, forming a disordered network. It is possible to take a crystalline solid and convert it into an amorphous solid by bombarding it with high-kinetic-energy ions. Under certain conditions of composition and temperature, interdiffusion (mixing on an atomic scale) between crystalline layers can produce an amorphous phase. Pyrolysis and electrolysis are other methods that can be used.

ATOMIC-SCALE STRUCTURE

The absence of long-range order is the defining characteristic of the atomic arrangement in amorphous solids. However, because of the absence in glasses of long parallel rows and flat parallel planes of atoms, it is extremely difficult to determine details of the atomic arrangement with the structure-probing techniques (such as X-ray diffraction) that are so successful for crystals. For glasses the information obtained from such structure-probing experiments is contained in a curve called the radial distribution function (RDF).

The radial distribution function

Figure 34 shows a comparison of the experimentally determined RDFs of the crystalline and amorphous forms of germanium, an elemental semiconductor similar to silicon. The heavy curve labeled a-Ge corresponds to amorphous germanium; the light curve labeled c-Ge corresponds to crystalline germanium. The significance of the RDF is that it gives the probability of neighbouring atoms being located at various distances from an average atom. The horizontal axis in the figure specifies the distance from a given atom; the vertical axis is proportional to the average number of atoms found at each distance. (The distance scale is expressed in angstrom units; one angstrom equals 10^{-8} centimetre.) The curve for crystalline germanium displays sharp peaks over the full range shown, corresponding to well-defined shells of neighbouring atoms at specific distances, which arise from the long-range regularity of the crystal's atomic arrangement. Amorphous germanium exhibits a close-in sharp peak corresponding to the nearest-neighbour atoms (there are four nearest neighbours in both c-Ge and a-Ge), but at larger distances the undulations in the RDF curve become washed out owing to the absence of long-range order. The first, sharp, nearest-neighbour peak in a-Ge is identical to the corresponding peak in c-Ge, showing that the short-range order in the amorphous form of solid germanium is as well-defined as it is in the crystalline form.

The detailed shape of the a-Ge RDF curve of Figure 34 is the input used in the difficult task of developing a model for the atomic arrangement in amorphous germanium. The normal procedure is to construct a model of the structure and then to calculate from the model's atomic positions a theoretical RDF curve. This calculated RDF is then compared to the experimental curve (which provides the definitive test of the validity of the model). Computer-assisted refinements are then made in the model in order to improve the agreement between the model-dependent theoretical RDF and the experimentally observed RDF. This program has been successfully carried out for many amorphous solids, so there is now much that is known about their atomic-scale structure. In contrast to the complete information available for crystals, however, the structural knowledge of glasses still contains gaps.

Amorphous solids, like crystalline solids, exhibit a wide

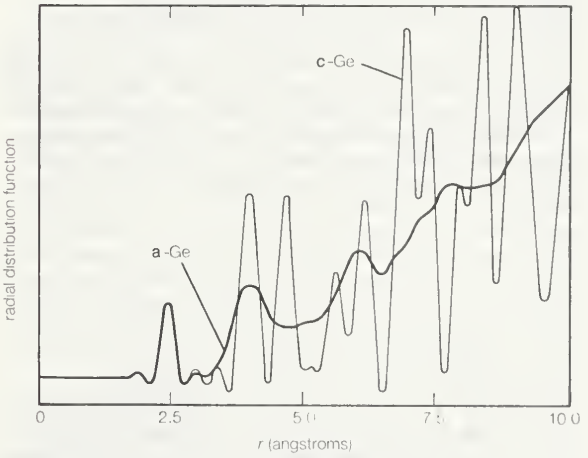

Figure 34: Comparison of the atomic radial distribution functions of crystalline (c-Ge) and amorphous (a-Ge) germanium. The value of the function at each distance r from a given atom is proportional to the number of atoms found at that distance.

Models of atomic-scale structure

variety of atomic-scale structures. Most of these can be recognized as falling within one or another of three broad classes of structure associated with the following models: (1) the continuous random-network model, applicable to covalently bonded glasses, such as amorphous silicon and the oxide glasses, (2) the random-coil model, applicable to the many polymer-chain organic glasses, such as polystyrene, and (3) the random close-packing model, applicable to metallic glasses, such as $Au_{0.8}Si_{0.2}$ gold-silicon. These are the names in conventional use for the models. Although each of them contains the word random, the well-defined short-range order means that they are not random in the sense that the gas structure of Figure 30C is random.

An illustration of the continuous random-network model is shown in Figure 35A and of the random-coil model in Figure 35B. Figure 35A reproduces a famous diagram published by W.H. Zachariasen in 1932. It is for a hypothetical two-dimensional A_2B_3 glass in which every A atom is bonded to three B atoms and every B atom to two A atoms. This picture bears a reasonable resemblance to current models for the arsenic chalcogenide glasses As_2S_3 and As_2Se_3. (Sulfur, S, and selenium, Se, belong to the group of elements called chalcogens.) The model was introduced as a schematic analogue for the network structure of the oxide glasses. The prototypical oxide glass is amorphous SiO_2, or silica glass. (Quartz, which is present in sand, is a crystalline form of SiO_2.) In amorphous SiO_2 each silicon atom is bonded to four oxygen atoms, and each oxygen atom is bonded to two silicon atoms. This structure is difficult to represent in a two-dimensional picture, but Figure 35A is a useful analogue with the hollow circles representing oxygen atoms and the small solid dots representing silicon atoms. The fourth bond originating at each silicon can be imagined to be out of the plane of the diagram.

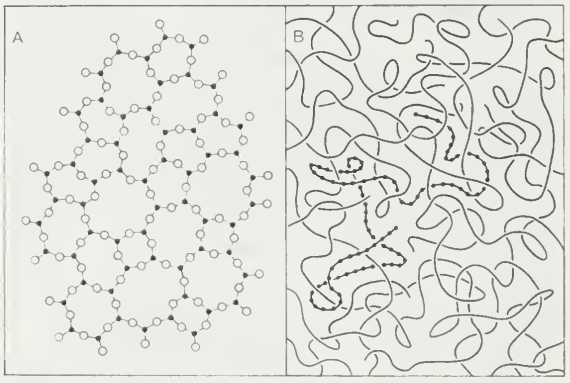

Figure 35: *Two basic models for the atomic-scale structure of amorphous solids.*
(A) The continuous random-network model for network glasses, and (B) the random-coil model for polymeric glasses.

The network structure shown in Figure 35A clearly demonstrates how short-range order (note the triangle of neighbours surrounding each solid dot) is compatible with the absence of long-range order. At the bridging oxygen atoms, the bond angles have some flexibility, so it is easy to continue the network. Common oxide glasses are chemically more complex than SiO_2, as discussed in the next section. Chemical species such as phosphorus and germanium, which (like silicon) enter into the structure of the network by forming strong chemical bonds with oxygen atoms, are called network formers. Chemical species such as sodium and calcium, which do not bond directly to the network but which simply sit (in ionic form) within its interstitial holes, are called network modifiers.

A large fraction of the everyday materials called plastics are amorphous solids composed of long-chain molecules known as polymers. Each polymer chain has a backbone consisting of a string of many (up to roughly 100,000) carbon atoms bonded to each other. These organic polymeric glasses are present in innumerable familiar molded products (*e.g.*, pens, tires, toys, appliance bodies, building materials, and automobile and airplane parts). The random-coil model of Figure 35B, first proposed in 1949 by P.J. Flory (who later received a Nobel Prize in Chemistry for his pioneering work on polymers), is the established structural model for this important class of amorphous solids. As schematically sketched in the figure, the structure consists of intermeshed, entangled polymer chains. The chain configurations are well-defined, statistically, by a mathematical trajectory called a three-dimensional random walk.

The third important structural model, the random close-packing model for metallic glasses, is difficult to illustrate with a simple diagram. Roughly speaking, it is similar to the structure that arises when a bunch of marbles are swiftly scrunched together in a paper bag. (R.Z.)

PROPERTIES OF OXIDE GLASSES

The wide range of the properties of glasses depends on their composition, and special effects result from the presence of various modifying agents in certain basic glass-forming materials (see above *Atomic-scale structure*).

Silica glass formers

One of the most important glass formers is silica (SiO_2). Pure crystalline silica melts at 1,710° C. In pure form, silica glass exhibits such properties as low thermal expansion, high softening temperatures, and excellent chemical and electrical resistance. In pure form it is relatively transparent over a wide range of wavelengths to visible and ultraviolet light and to ultrasonic waves.

The high viscosity (see below) and melting temperature of silica glass are affected by the presence or absence of other materials. For example, if certain materials called fluxes are added, the most important being soda (Na_2O), both viscosity and melting temperature can be reduced. If too much soda is added, the resulting glass is readily attacked by water, but, if there are suitable amounts of stabilizing oxides, such as lime (CaO) and magnesia (MgO), the glass becomes more durable. Most commercial glass has a soda-lime-silica composition and is produced in vast quantities for plate and sheet glass, containers, and lightbulbs.

In soda-lime-silica glasses, if lime is replaced by lead oxide (PbO) and if potash (K_2O) is used as a partial replacement for soda, lead-alkali-silicate glasses result that have lower softening points than lime glasses. The refractive indices, dispersive powers, and electrical resistance of these glasses are generally much greater than those of soda-lime-silica glasses.

Boric oxide (B_2O_3), itself a glass former, acts as a flux (*i.e.*, lowers the working temperature) when present in silica and forms borosilicate glass, and the substitution of small percentages of alkali and alumina increases the chemical stability. It also exhibits low thermal expansion, high dielectric strength, and high softening temperature.

Aluminosilicate glasses find applications similar to those of borosilicates, but the former can stand higher operating temperatures; glasses with relatively high alumina contents and no boric oxide are exceptionally resistant to alkalies.

Nonsilica glass formers

The above glasses all have silica as the glass former. With other glass formers, glasses have special properties. For example, if boric oxide is present, X rays are transmitted and rare-earth glasses will exhibit low dispersion and a high refractive index. Phosphate glasses (used as optical glasses) based on phosphorus pentoxide (P_2O_5) are highly resistant to hydrofluoric acid and act as efficient heat absorbers when iron oxide is added. Table 4 gives the compositions and physical properties of some typical commercial oxide glasses of the types described. (R.W.D./R.Z.)

PROPERTIES AND APPLICATIONS OF AMORPHOUS SOLIDS

The following sections discuss technological applications of amorphous solids in connection with the properties that make those applications possible. It is important to understand that, although differences do exist between the properties of amorphous and crystalline solids, it is nevertheless broadly true that amorphous solids exhibit essentially the full range of properties and phenomena exhibited by crystalline solids. There are amorphous-solid metals, semiconductors, and insulators; there are transparent glasses and opaque glasses; and there are superconducting amorphous solids and ferromagnetic amorphous solids.

Table 4: Characteristics of Oxide Glasses

	fused silica	soda-lime-silica	borosilicate	aluminosilicate	lead
Approximate composition*	SiO_2 99.9% H_2O 0.1%	SiO_2 73% Al_2O_3 1% Na_2O_2 17% MgO 4% CaO 5%	SiO_2 81% Al_2O_3 2% B_2O_3 13% Na_2O 4%	SiO_2 62% Al_2O_3 17% B_2O_3 5% Na_2O 1% MgO 7% CaO 8%	SiO_2 56% Al_2O_3 2% Na_2O 4% K_2O 9% PbO 29%
Coefficient of thermal expansion (linear expansion per °C × 10^7)	5.5	93	33	42	89
Strain point † (°C; viscosity about $10^{14.5}$ poise)	990	470	515	670	395
Annealing point ‡ (°C; viscosity about 10^{13} poise)	1,050	510	565	715	435
Softening point §‖ (°C; viscosity about $10^{7.65}$ poise)	1,580	695	820	915	630
Young's modulus (lbs per sq in. × 10^6)	10.5	10	9.1	12.7	8.6
Refractive index (for sodium D line)	1.459	1.512	1.474	1.530	1.560
Dielectric constant (at 10^6 cycles per second and 20° C)	3.8	7.2	4.6	7.2	6.7
Density (g/cm³)	2.20	2.47	2.23	2.52	3.05

*These compositions are typical of the various glass types. †Temperature at which internal stresses are reduced significantly over a few hours. ‡Temperature at which internal stresses are reduced significantly over a few minutes. §Temperature at which glass will rapidly deform under its own weight. ‖The strain point and annealing point roughly define the annealing range.

Some of the general differences between the properties of crystals and glasses, in addition to the fundamental one of the glass transition (as discussed above in connection with Figure 31 and also below with regard to its value in technological settings), are noted here. The atomic-scale disorder present in a metallic glass causes its electrical conductivity to be lower than the conductivity of the corresponding crystalline metal, because the structural disorder impedes the motion of the mobile electrons that make up the electrical current. (This lower electrical conductivity for the amorphous metal can be an advantage in some situations, as discussed below in the section *Magnetic glasses.*) For a similar reason, the thermal conductivity of an insulating glass is lower than that of the corresponding crystalline insulator; glasses thus make good thermal insulators. Crystals and glasses also differ systematically in their optical spectra, which are the curves that describe the wavelength dependence of the degree to which the solid absorbs infrared, visible, or ultraviolet light. Although the overall spectra are often similar, crystal spectra typically exhibit sharp peaks and other features that specifically arise as a consequence of the long-range order of the crystal's atomic-scale structure. These sharp features are absent in the optical spectra of amorphous solids.

The continuous liquid-to-solid transition near T_g, the glass transition, has a profound significance in connection with classical applications of glasses. While crystallization abruptly transforms a mobile, low-viscosity liquid to a crystalline solid at T_f, near T_g the liquid viscosity increases continuously through a large range in the transformation to an amorphous solid. Viscosity, expressed in units of poise, is used in Table 4 to specify characteristic working temperatures in the processing of the liquid precursors

Viscosity of glasses

of various oxide glasses. A poise is the centimetre-gram-second (cgs) unit of viscosity. It expresses the force needed to maintain a unit velocity difference between parallel plates separated by one centimetre of fluid: one poise equals one dyne-second per square centimetre. Molten glass may have a viscosity of 10^{13} poise (similar to honey on a cold day), and it quickly gets stiffer when cooled since the viscosity steeply increases with decreasing temperature. The ability to "tune" the viscosity of the melt (by changing temperature) allows glass to be conveniently processed and worked into desired shapes; glassblowing is a classic example of the usefulness of this widely exploited property.

Table 5 lists some important technological uses of amorphous solids. In addition to the application, the general type of amorphous solid used, and the material properties that make the application possible, the table also includes information about the chemical compositions of typical materials employed in these techniques. While the first entry—namely, window glass—represents the present status of a centuries-old technology, the other entries correspond to technologies that have blossomed during the second half of the 20th century. A significant theme of Table 5 is the role of amorphous solids in applications calling for large-area sheets or films. Amorphous solids often have great advantages over crystalline solids in such applications, since their use avoids the functional problems associated with polycrystallinity or the expense of preparing large single crystals. Thus, while it would be prohibitively expensive to fabricate large windows out of crystalline SiO_2 (quartz), it is practical to do so using SiO_2-based silicate glasses.

Transparent glasses. The terms glass and window glass are often used interchangeably in everyday language, so

Table 5: Some Technological Applications of Amorphous Solids

type of amorphous solid	representative material	application	special properties
Oxide glass	$(SiO_2)_{0.8}(Na_2O)_{0.2}$	window glass	transparency, solidity, formability as large sheets
Oxide glass	$(SiO_2)_{0.9}(GeO_2)_{0.1}$	fibre-optic waveguides for communications networks	ultratransparency, purity, formability as uniform fibres
Organic polymer	polystyrene	structural materials, plastics	strength, light weight, ease of processing
Chalcogenide glass	Se, As_2Se_3	copiers and laser printers	photoconductivity, formability as large-area films
Amorphous semiconductor	$Si_{0.9}H_{0.1}$	solar cells, copiers, flat-panel displays	photovoltaic optical properties, large-area thin films, semiconducting properties
Metallic glass	$Fe_{0.8}B_{0.2}$	transformer cores	ferromagnetism, low power loss, formability as long ribbons

familiar is this ancient architectural application of amorphous solids. Not only are oxide glasses, such as those characterized in Table 4, excellent for letting light in, they are also good for keeping cold out, because (as mentioned above) they are efficient thermal insulators.

The second application in Table 5 represents a modern development that carries the property of optical transparency to a phenomenal level. The transparency of the extraordinarily pure glasses that have been developed for fibre-optic telecommunications is so great that, at certain wavelengths, light can pass through 1 kilometre (0.6 mile) of glass and still retain 95 percent of its original intensity.

Fibre-optic telecommunications

Glass fibres (transmitting optical signals) are now doing what copper wires (transmitting electrical signals) once did and are doing it more efficiently: carrying telephone messages around the planet. How this is done is schematically indicated in Figure 36. Digital electrical pulses produced by encoding of the voice-driven electrical signal are converted into light pulses by a semiconductor laser coupled to one end of the optical fibre. The signal is then transmitted over a long length of fibre as a stream of light pulses. At the far end it is converted back into electrical pulses and then into sound.

The glass fibre is somewhat thinner than a human hair. The simplest type, as sketched in the upper left of the figure, has a central core of ultratransparent glass surrounded by a coaxial cladding of a glass having a lower refractive index, n. This ensures that light rays propagating within the core, at small angles relative to the fibre axis, do not leak out but instead are 100 percent reflected at the core-cladding interface by the optical effect known as total internal reflection.

The great advantage provided by the substitution of light-transmitting fibres of ultratransparent oxide glass for electricity-transmitting wires of crystalline copper is that a single optical fibre can carry many more simultaneous conversations than can a thick cable packed with copper wires. This is the case because light waves oscillate at enormously high frequencies (about 2×10^{14} cycles per second for the infrared light generally used for fibre-optic telecommunications). This allows the light-wave signal carrier to be modulated at very high frequencies and to transmit a high volume of information traffic. Fibre-optic communications have greatly expanded the information-transmitting capacity of the world's telecommunications networks.

Polymeric structural materials. Polystyrene, the organic polymer listed in Table 5, is a prototypical example of a polymeric glass. These glasses, whose atomic-scale structure has been discussed in connection with Figure 35B, make up a broad class of lightweight structural materials important in the automotive, aerospace, and construction industries. These materials are also ubiquitous in everyday experience as plastic molded objects. The quantity of polymer materials produced each year, measured in terms of volume, exceeds the quantity of steel produced.

Polystyrene is among the most important of the thermoplastic materials that, when heated (to the vicinity of the glass transition temperature), soften and flow controllably, enabling them to be processed at high speeds and on a large scale in the manufacture of molded products. The chemical formula of a polystyrene chain may be written as $(CH_2CHC_6H_5)_N$. The building block (inside the parentheses) consists of two backbone carbon atoms to which three hydrogen atoms and one phenyl (C_6H_5) ring are bonded as side groups. The polymerization index N reaches values above 10^5. Polystyrene is a purely hydrocarbon polymer (*i.e.*, it contains only hydrogen and carbon); most organic polymers contain additional chemical components.

Amorphous semiconductors in electronics. Amorphous semiconductors, in the form of thin films prepared by methods such as that shown in Figure 32D, are important in applications requiring large areas of electronically active material. The first electronic application of amorphous semiconductors to occur on a large scale was in xerography (or electrostatic imaging), the process that provides the basis of plain-paper copiers. Amorphous selenium (Se) and, later, amorphous arsenic selenide (As_2Se_3) were used to form the thin-film, large-area photoconducting element that lies at the heart of the xerographic process. The photoconductor, which is an electrical insulator in the absence of light but which conducts electricity when illuminated, is exposed to an image of the document to be copied. Throughout the world—in offices, libraries, schools, and so forth—the xerographic process makes more than five billion copies every day. This process is also widely used in laser printers, in which the photoconductor is exposed to a digitally controlled on-and-off laser beam that is raster scanned (like the electron beam in a television tube) over the photoconductor surface.

Applications in xerography

Although still in use, selenium and arsenic selenide have been joined by other amorphous materials in this important technology. Polymeric organic glasses, in the form of thin films, are now used in multilayer photoconductor configurations in which the light is absorbed in one layer and electrical charge is transported through an adjacent layer. Both layers are formed of amorphous polymer films, and these photoreceptors can be made in the form of flexible belts.

Amorphous silicon thin films are used in solar cells that power handheld calculators. This important amorphous semiconductor is also used as the image sensor in facsimile ("fax") machines, and it serves as the photoreceptor in some xerographic copiers. All these applications exploit the ability of amorphous silicon to be vapour-deposited in the form of large-area thin films. As shown in Table 5, the practical form of this amorphous semiconductor is not pure silicon but a silicon-hydrogen alloy containing 10 percent hydrogen. The key role played by hydrogen, in what is now called hydrogenated amorphous silicon, emerged in a scientific puzzle that took years to solve. Stated briefly, hydrogen eliminates the electronic defects that are intrinsic to pure amorphous silicon.

Hydrogenated amorphous silicon also is used in high-

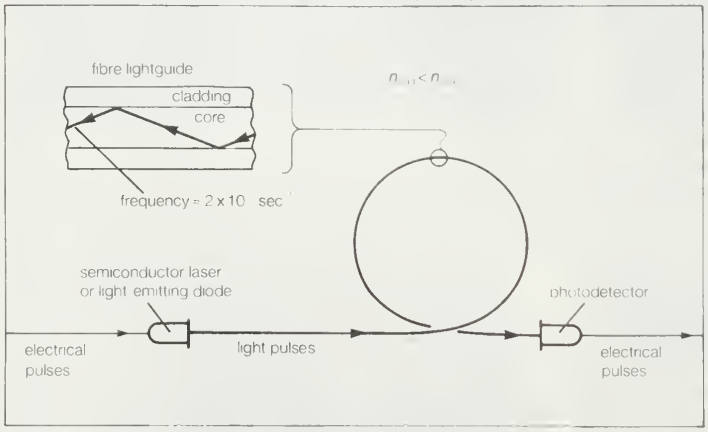

Figure 36: The use of ultratransparent glass fibres in telecommunications networks.

resolution flat-panel displays for computer monitors and for television screens. In such applications the large-area amorphous-semiconductor thin film is etched into an array of many tiny units, each of which forms the active element of a transistor that electronically turns on or off a small pixel (picture element) of a liquid-crystal display.

Magnetic glasses. The last entry in Table 5 is an application of metallic glasses having magnetic properties. These are typically iron-rich amorphous solids with compositions such as $Fe_{0.8}B_{0.2}$ iron-boron and $Fe_{0.8}B_{0.1}Si_{0.1}$ iron-boron-silicon. They are readily formed as long metallic glass ribbons by melt spinning or as wide sheets by planar flow casting. Ferromagnetic glasses are mechanically hard materials, but they are magnetically soft, meaning that they are easily magnetized by small magnetic fields. Also, because of their disordered atomic-scale structure, they have higher electrical resistance than conventional (crystalline) magnetic materials. The three attributes of ease of manufacture, magnetic softness, and high electrical resistance make magnetic glasses extremely suitable for use in the magnetic cores of electrical power transformers. High electrical resistance (which arises here as a direct consequence of amorphicity) is a crucial property in this application, because it minimizes unwanted electrical eddy currents and cuts down on power losses. For these reasons, sheets of iron-based magnetic glasses are used as transformer-core laminations in electrical power applications.

Electrical power applications

Thin films of magnetic glass are finding use in many other applications. These include magnetic recording media for audio and video digital recording, as well as recording heads used with magnetic disks. (R.Z.)

LIQUID STATE

The most obvious physical properties of a liquid are its retention of volume and its conformation to the shape of its container. When a liquid substance is poured into a vessel, it takes the shape of the vessel, and, as long as the substance stays in the liquid state, it will remain inside the vessel. Furthermore, when a liquid is poured from one vessel to another, it retains its volume (as long as there is no vaporization or change in temperature) but not its shape. These properties serve as convenient criteria for distinguishing the liquid state from the solid and gaseous states. Gases, for example, expand to fill their container so that the volume they occupy is the same as that of the container. Solids retain both their shape and volume when moved from one container to another.

Liquids may be divided into two general categories: pure liquids and liquid mixtures. On Earth, water is the most abundant liquid, although much of the water with which organisms come into contact is not in pure form but is a mixture in which various substances are dissolved. Such mixtures include those fluids essential to life—blood, for example—beverages, and seawater. Seawater is a liquid mixture in which a variety of salts have been dissolved in water. Even though in pure form these salts are solids, in oceans they are part of the liquid phase. Thus, liquid mixtures contain substances that in their pure form may themselves be liquids, solids, or even gases.

The liquid state sometimes is described simply as the state that occurs between the solid and gaseous states, and for simple molecules this distinction is unambiguous. However, clear distinction between the liquid, gaseous, and solid states holds only for those substances whose molecules are composed of a small number of atoms. When the number exceeds about 20, the liquid may often be cooled below the true melting point to form a glass (see *Solid state: Amorphous solids*), which has many of the mechanical properties of a solid but lacks crystalline order. If the number of atoms in the molecule exceeds about 100–200, the classification into solid, liquid, and gas ceases to be useful. At low temperatures such substances are usually glasses or amorphous solids, and their rigidity falls with increasing temperature—*i.e.,* they do not have fixed melting points; some may, however, form true liquids. With these large molecules, the gaseous state is not attainable, because they decompose chemically before the temperature is high enough for the liquid to evaporate. Synthetic and natural high polymers (*e.g.,* nylon and rubber) behave in this way.

If the molecules are large, rigid, and either roughly planar or linear, as in cholesteryl acetate or *p*-azoxyanisole, the solid may melt to an anisotropic liquid (*i.e.,* one that is not uniform in all directions) in which the molecules are free to move about but have great difficulty in rotating. Such a state is called a liquid crystal, and the anisotropy produces changes of the refractive index (a measure of the change in direction of light when it passes from one medium into another) with the direction of the incident light and hence leads to unusual optical effects. Liquid crystals have found widespread applications in temperature-sensing devices and in displays for watches and calculators. However, no inorganic compounds and only about 5 percent of the known organic compounds form liquid crystals. The theory of normal liquids is, therefore, predominantly the theory of the behaviour of substances consisting of simple molecules.

A liquid lacks both the strong spatial order of a solid, though it has the high density of solids, and the absence of order of a gas that results from the low density of gases—*i.e.,* gas molecules are relatively free of each other's influence. The combination of high density and of partial order in liquids has led to difficulties in developing quantitatively acceptable theories of liquids. Understanding of the liquid state, as of all states of matter, came with the kinetic molecular theory, which stated that matter consisted of particles in constant motion and that this motion was the manifestation of thermal energy. The greater the thermal energy of the particle, the faster it moved.

In very general terms, the particles that constitute matter include molecules, atoms, ions, and electrons. In a gas these particles are far enough from one another and are moving fast enough to escape each other's influence, which may be of various kinds—such as attraction or repulsion due to electrical charges and specific forces of attraction that involve the electrons orbiting around atomic nuclei. The motion of particles is in a straight line, and the collisions that result occur with no loss of energy, although an exchange of energies may result between colliding particles. When a gas is cooled, its particles move more slowly, and those slow enough to linger in each other's vicinity will coalesce, because a force of attraction will overcome their lowered kinetic energy and, by definition, thermal energy. Each particle, when it joins others in the liquid state, gives up a measure of heat called the latent heat of liquefaction, but each continues to move at the same speed within the liquid as long as the temperature remains at the condensation point. The distances that the particles can travel in a liquid without colliding are on the order of molecular diameters. As the liquid is cooled, the particles move more slowly still, until at the freezing temperature the attractive energy produces so high a density that the liquid freezes into the solid state. They continue to vibrate, however, at the same speed as long as the temperature remains at the freezing point, and their latent heat of fusion is released in the freezing process. Heating a solid provides the particles with the heat of fusion necessary to allow them to escape one another's influence enough to move about in the liquid state. Further heating provides the liquid particles with their heat of evaporation, which enables them to escape one another completely and enter the vapour, or gaseous, state.

Transition to the liquid state

This starkly simplified view of the states of matter ignores many complicating factors, the most important being the fact that no two particles need be moving at the same speed in a gas, liquid, or solid and the related fact that even in a solid some particles may have acquired the energy necessary to exist as gas particles, while even in a gas some particles may be practically motionless for a

brief time. It is the average kinetic energy of the particles that must be considered, together with the fact that the motion is random. At the interface between liquid and gas and between liquid and solid, an exchange of particles is always taking place: slow gas molecules condensing at the liquid surface and fast liquid molecules escaping into the gas. An equilibrium state is reached in any closed system, so that the number of exchanges in either direction is the same. Because the kinetic energy of particles in the liquid state can be defined only in statistical terms (*i.e.*, every possible value can be found), discussion of the liquid (as well as the gaseous) state at the molecular level involves formulations in terms of probability functions.

Behaviour of pure liquids

When the temperature and pressure of a pure substance are fixed, the equilibrium state of the substance is also fixed. This is illustrated in Figure 37, which shows the phase diagram for pure argon. In the diagram a single phase is shown as an area, two as a line, and three as the intersection of the lines at the triple point, *T*. Along the line *TC*, called the vapour-pressure curve, liquid and vapour exist in equilibrium. The liquid region exists to the left and above this line while the gas, or vapour, region exists below it. At the upper extreme, this curve ends at the critical point, *C*. If line *TC* is crossed by moving directly from point *P* to *S*, there is a distinct phase change accompanied by abrupt changes in the physical properties of the substance (*e.g.*, density, heat capacity, viscosity, and dielectric constant) because the vapour and liquid phases have distinctly different properties. At the critical point, however, the vapour and liquid phases become identical, and above the critical point, the two phases are no longer distinct. Thus, if the substance moves from point *P* to *S* by the path *PQRS* so that no phase-change lines are crossed, the change in properties will be smooth and continuous, and the specific moment when the substance converts from a liquid to a gas is not clearly defined. In fact, the path *PQRS* demonstrates the essential continuity of state between liquid and gas, which differ in degree but which together constitute the single fluid state. Strictly speaking, the term liquid should be applied only to the denser of the two phases on the line *TC*, but it is generally extended to any dense fluid state at low temperatures—*i.e.*, to the area lying within the angle *CTM*.

The extension of line *TC* below the triple point is called the sublimation curve. It represents the equilibrium between solid and gas, and when the sublimation curve is crossed, the substance changes directly from solid to gas. This conversion occurs when dry ice (solid carbon dioxide) vaporizes at atmospheric pressure to form gaseous carbon dioxide because the triple-point pressure for carbon dioxide is greater than atmospheric pressure. Line *TM* is the melting curve and represents an equilibrium between solid and liquid; when this curve is crossed from left to right, solid changes to liquid with the associated abrupt change in properties.

The melting curve is initially much steeper than the vapour-pressure curve; hence, as the pressure is changed, the temperature does not change much, and the melting temperature is little affected by pressure. No substance has been found to have a critical point on this line, and there are theoretical reasons for supposing that it continues indefinitely to high temperatures and pressures, until the substance is so compressed that the molecules break up into atoms, ions, and electrons. At pressures above 10^6 bars (one bar is equal to 0.987 atmosphere, where one atmosphere is the pressure exerted by the air at sea level), it is believed that most substances pass into a metallic state.

It is possible to cool a gas at constant pressure to a temperature lower than that of the vapour-pressure line without producing immediate condensation, since the liquid phase forms readily only in the presence of suitable nuclei (*e.g.*, dust particles or ions) about which the drops can grow. Unless the gas is scrupulously cleaned, such nuclei remain; a subcooled vapour is unstable and will ultimately condense. It is similarly possible to superheat a liquid to a temperature where, though still a liquid, the gas

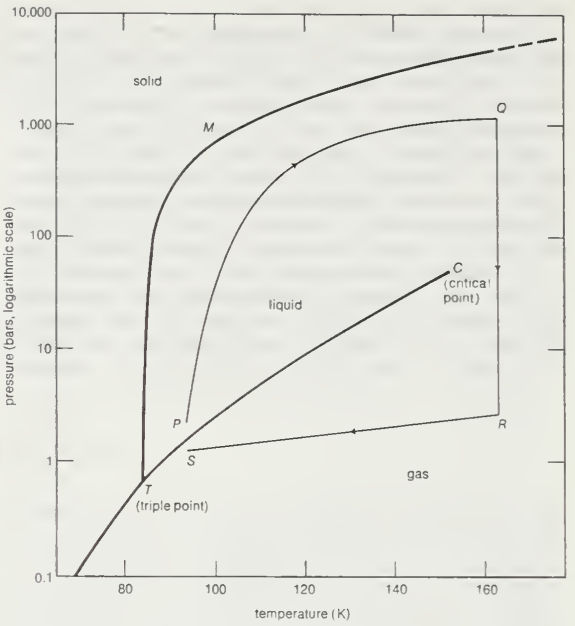

Figure 37: *Phase diagram of argon.*
Heavy lines show the boundaries between liquid and gas (*TC*) and between liquid and solid (*TM*). Curve *PQRS* describes a path from a typically liquid state (*P*) to a typically gaseous state (*S*; see text).

is the stable phase. Again, this occurs most readily with clean liquids heated in smooth vessels, because bubble formation occurs around foreign particles or sharp points. When the superheated liquid changes to gas, it does so with almost explosive violence. A liquid also may be subcooled to below its freezing temperature.

To a certain extent the behaviour of all substances is similar to that described in Figure 37. The parameters that vary from substance to substance are the particular values of the triple-point and critical-point temperature and pressure, the size of the various regions, and the slopes of the lines. Triple-point temperatures range from 14 K (0 K equals −273.15° C [−459.67° F]), for hydrogen to temperatures too high for accurate measurement. Triple-point pressures are generally low, that of carbon dioxide at 5.2 bars being one of the highest. Most are around 10^{-3} bar, and those of some hydrocarbons are as low as 10^{-7} bar. The normal melting point of a substance is defined as the melting temperature at a pressure of one atmosphere (equivalent to 1.01325 bars); it differs little from the triple-point temperature, because of the steepness of melting lines (*TM* in Figure 37). Critical temperatures (the maximum temperature at which a gas can be liquefied by pressure) range from 5.2 K, for helium, to temperatures too high to measure. Critical pressures (the vapour pressure at the critical temperature) are generally about 40–100 bars. The normal boiling point is the temperature at which the vapour pressure reaches one atmosphere. The normal liquid range is defined as the temperature interval between the normal melting point and the normal boiling point, but such a restriction is artificial, the true liquid range being from triple point to critical point. Substances whose triple-point pressures are above atmospheric (*e.g.*, carbon dioxide) have no normal liquid range but sublime at atmospheric pressure.

Triple-point temperature

Each of the three two-phase lines in Figure 37 can be described by the Clapeyron equation:

$$\frac{dp}{dT} = \frac{\Delta H}{T\Delta V} \qquad (1)$$

In this equation, dp/dT is the slope of the curve under consideration—*i.e.*, either the melting, sublimation, or vapour-pressure curve. ΔH is the latent heat required for the phase change, and ΔV is the change in volume associated with the phase change. Thus, for the sublimation and vapour-pressure curves, since ΔH and ΔV are both positive (*i.e.*, heat is required for vaporization, and the volume increases on vaporization), the slope is always

positive. Although not apparent from Figure 37, the slope of the sublimation curve immediately below the triple point is greater than the slope of the vapour-pressure curve immediately above it, so that the vapour-pressure curve is not continuous through the triple point. This is consistent with equation (1) because the heat of sublimation for a substance is somewhat larger than its heat of vaporization. The slope of the melting line is usually positive, but there are a few substances, such as water and bismuth, for which the melting-line slope is negative. The negative melting-line slope is consistent with equation (1) because, for these two substances, the density of the solid is less than the density of the liquid. This is the reason ice floats. For water, this negative volume change (*i.e.*, shrinking) persists to 2.1 kilobars and −22° C, at which point the normal form of ice changes to a denser form, and thereafter the change in volume on melting is positive.

At the critical point the liquid is identical to the vapour phase, and near the critical point the liquid behaviour is somewhat similar to vapour-phase behaviour. While the particular values of the critical temperature and pressure vary from substance to substance, the nature of the behaviour in the vicinity of the critical point is similar for all compounds. This fact has led to a method that is commonly referred to as the law of corresponding states. Roughly speaking, this approach presumes that, if the phase diagram is plotted using reduced variables, the behaviour of all substances will be more or less the same. Reduced variables are defined by dividing the actual variable by its associated critical constant: the reduced temperature, T_r, equals T/T_c, and the reduced pressure, p_r, equals p/p_c. Then for all substances the critical point occurs at a value of T_r and p_r equal to unity. This approach has been used successfully to develop equations to correlate and predict a number of liquid-phase properties including vapour pressures, saturated and compressed liquid densities, heat capacities, and latent heats of vaporization. The corresponding states approach works remarkably well at temperatures between the normal boiling point and the critical point for many compounds but tends to break down near and below the triple-point temperature. At these temperatures the liquid is influenced more by the behaviour of the solid, which has not been successfully correlated by corresponding states methods.

Law of corresponding states

Many of the properties of a liquid near its triple point are closer to those of the solid than to those of the gas. It has a high density (typically 0.5–1.5 grams per cubic centimetre [0.02–0.05 pound per cubic inch]), a high refractive index (which varies from 1.3 to 1.8 for liquids), a high heat capacity at constant pressure (two to four joules per gram per kelvin, one joule being equal to 0.239 calorie), and a low compressibility ($0.5–1 \times 10^{-4}$ per bar). The compressibility falls to values characteristic of a solid (0.1×10^{-4} per bar or less) as the pressure increases. A simple and widely used equation describes the change of specific volume with pressure. If $V(p)$ is the volume at pressure p, $V(0)$ is volume at zero pressure, and A and B are positive parameters (constants whose values may be arbitrarily assigned), then the difference in volume resulting from a change in pressure equals the product of A, the pressure, and the volume at zero pressure, divided by the sum of B and the pressure. This is written:

$$V(0) - V(p) = \frac{ApV(0)}{(B+p)}. \qquad (2)$$

The pressure parameter B is close to the pressure at which the compressibility has fallen to half its initial value and is generally about 500 bars for liquids near their triple points. It falls rapidly with increasing temperature.

As a liquid is heated along its vapour-pressure curve, TC, its density falls and its compressibility rises. Conversely, the density of the saturated vapour in equilibrium with the liquid rises; *i.e.*, the number of gas molecules in a fixed space above the liquid increases. Liquid and gas states approach each other with increasing rapidity as the temperature approaches C, until at this point they become identical and have a density about one-third that of the liquid at point T. The change of saturated-gas density (ρ_g) and liquid density (ρ_l) with temperature T can be expressed by a simple equation when the temperature is close to critical. If ρ_c is the density at the critical temperature T_c, then the difference between densities equals the difference between temperatures raised to a factor called beta, β:

$$(\rho_l - \rho_c) = (\rho_c - \rho_g) = (T_c - T)^{\beta}, \qquad (3)$$

where β is about 0.34. The compressibility and the heat capacity of the gas at constant pressure (C_p) become infinite as T approaches T_c from above along the path of constant density. The infinite compressibility implies that the pressure no longer restrains local fluctuations of density. The fluctuations grow to such an extent that their size is comparable with the wavelength of light, which is therefore strongly scattered. Hence, at the critical point, a normally transparent liquid is almost opaque and usually dark brown in colour. The classical description of the critical point and the results of modern measurement do not agree in detail, but recent considerations of thermodynamic stability show that there are certain regularities in behaviour that are common to all substances.

Between a liquid and its corresponding vapour there is a dividing surface that has a measurable tension; work must be done to increase the area of the surface at constant temperature. Hence, in the absence of gravity or during free fall, the equilibrium shape of a volume of liquid is one that has a minimum area—*i.e.*, a sphere. In the Earth's field this shape is found only for small drops, for which the gravitational forces, since they are proportional to the volume, are negligible compared with surface forces, which are proportional to the area. The surface tension falls with rising temperature and vanishes at the critical point. There is a similar dividing surface between two immiscible liquids, but this usually has lower tension. It is believed that there is a tension also between a liquid and a solid, though it is not directly measurable because of the rigidity of the solid; it may be inferred, however, under certain assumptions, from the angle of contact between the liquid and the solid (*i.e.*, the angle at which the liquid's surface meets the solid). If this angle is zero, the liquid surface is parallel to the solid surface and is said to wet the solid completely.

Shape of drops

MOLECULAR STRUCTURE OF LIQUIDS

For a complete understanding of the liquid state of matter, an understanding of behaviour on the molecular level is necessary. Such behaviour is characterized by two quantities called the intermolecular pair potential function, u, and the radial distribution function, g. The pair potential gives information about the energy due to the interaction of a pair of molecules and is a function of the distance r between their centres. Information about the structure or the distances between pairs of molecules is contained in the radial distribution function. If g and u are known for a substance, macroscopic properties can be calculated.

Radial distribution function

In an ideal gas—where there are no forces between molecules, and the volume of the molecules is negligible—g is unity, which means that the chance of encountering a second molecule when moving away from a central molecule is independent of position. In a solid, g takes on discrete values at distances that correspond to the locations associated with the solid's crystal structure. Liquids possess neither the completely ordered structure of a solid crystal nor the complete randomness of an ideal gas. The structure in a liquid is intermediate to these two extremes—*i.e.*, the molecules in a liquid are free to move about, but there is some order because they remain relatively close to one another. Although there are an infinite number of possible positions one molecule may assume with respect to another, some are more likely than others. This is illustrated by Figure 38, which shows an example of the radial distribution function for the dense packing typical of liquids. In this figure, g is a measure of the probability of finding the centre of one molecule at a distance r from the centre of a second molecule. For values of r less than those of the molecular diameter, d, g goes to zero. This is consistent with the fact that two molecules cannot occupy the same space. The most likely location for a second molecule with respect to a central molecule is slightly more than one molecular diameter away, which

reflects the fact that in liquids the molecules are packed almost against one another. The second most likely location is a little more than two molecular diameters away, but beyond the third layer preferred locations damp out, and the chance of finding the centre of a molecule becomes independent of position.

The pair potential function, u, is a large positive number for r less than d, assumes a minimum value at the most preferred location (this corresponds to the maximum of the curve in Figure 38), and damps out to zero as r approaches infinity. The large positive value of u corresponds to a strong repulsion, while the minimum corresponds to the net result of repulsive and attractive forces.

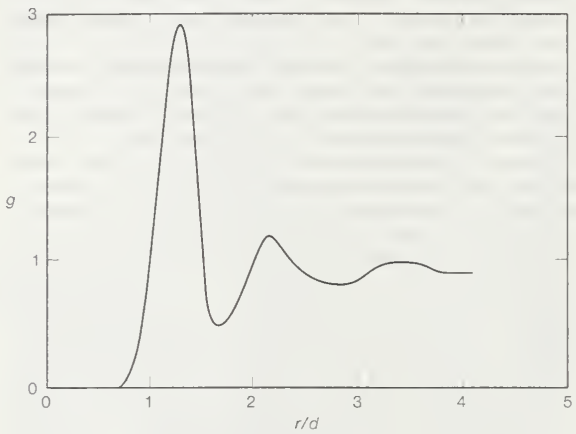

Figure 38: *Radial distribution function for a dense fluid.* The radial distribution function, g, is a measure of the probability of finding the centre of one molecule at a distance r from a central molecule. The molecular diameter is d.

There are two methods of measuring the radial distribution function g: first, by X-ray or neutron diffraction from simple fluids and, second, by computer simulation of the molecular structure and motions in a liquid. In the first, the liquid is exposed to a specific, single wavelength (monochromatic) radiation, and the observed results are then subjected to a mathematical treatment known as a Fourier transform.

Use of a computer model

The second method of obtaining the radial distribution function g supposes that the energy of interaction, u, for the liquid under study is known. A computer model of a liquid is set up, in which between 100 and 1,000 molecules are contained within a cube. There are now two methods of proceeding: by Monte Carlo calculation or by what is called molecular dynamics; only the latter is discussed here. Each molecule is assigned a random position and velocity, and Newton's equations of motion are solved to calculate the path of each molecule in the changing field of all the others. A molecule that leaves the cell is deemed to be replaced by a new one with equal velocity entering through the corresponding point on the opposite wall. After a few collisions per molecule, the distribution of velocities conforms with equations worked out by the Scottish physicist James Clerk Maxwell, and after a longer time the mean positions are those appropriate to the density and mean kinetic energy (*i.e.*, temperature) of the liquid. Functions such as the radial distribution function g can now be evaluated by taking suitable averages as the system evolves in time. Since 1958 such computer experiments have added more to the knowledge of the molecular structure of simple liquids than all the theoretical work of the previous century and continue to be an active area of research for not only pure liquids but liquid mixtures as well.

SPEED OF SOUND AND ELECTRIC PROPERTIES

A sound wave is a series of longitudinal compressions and expansions that travels through a liquid at a speed of about one kilometre per second (0.62 mile per second), or about three times the speed of sound in air. If the frequency is not too high, the compressions and expansions are adiabatic (*i.e.*, the changes take place without transfer of heat) and reversible. Conduction of energy from the hot (compressed) to the cold (expanded) regions of the liquid introduces irreversible effects, which are dissipative, and thus such conduction leads to the absorption of the sound. A longitudinal compression (in the direction of the wave) is a combination of a uniform compression and a shearing stress (a force that causes one plane of a substance to glide past an adjacent plane). Hence, both bulk and shear viscosity also govern the propagation of sound in a liquid.

If a liquid is placed in a static electric field, the field exerts a force on any free carriers of electric charge in the liquid, and the liquid, therefore, conducts electricity. Such carriers are of two kinds: mobile electrons and ions. The former are present in abundance in liquid metals, which have conductivities that are generally about one-third of the conductivity of the corresponding solid. The decrease in conductivity upon melting arises from the greater disorder of the positive ions in the liquid and hence their greater ability to scatter electrons. The contribution of the ions is small, less than 5 percent in most liquid metals, but it is the sole cause of conductivity in molten salts and in their aqueous solutions. Such conductivities vary widely but are much lower than those of liquid metals.

Nonionic liquids

Nonionic liquids (those composed of molecules that do not dissociate into ions) have negligible conductivities, but they are polarized by an electric field; that is, the liquid develops positive and negative poles and also a dipole moment (which is the product of the pole strength and the distance between the poles) that is oriented against the field, from which the liquid acquires energy. This polarization is of three kinds: electron, atomic, and orientation. In electron polarization the electrons in each atom are displaced from their usual positions, giving each molecule a small dipole moment. The contribution of electron polarization to the dielectric constant (see below *Solutions and solubilities: Classes of solutions: Electrolytes and nonelectrolytes*) of the liquid is numerically equal to the square root of its refractive index. The second effect, atomic polarization, arises because there is a relative change in the mean positions of the atomic nuclei within the molecules. This generally small effect is observed at radio frequencies but not at optical, and so it is missing from the refractive index. The third effect, orientation polarization, occurs with molecules that have permanent dipole moments. These molecules are partially aligned by the field and contribute heavily to the polarization. Thus, the dielectric constant of a nonpolar liquid, such as a hydrocarbon, is about 2, that of a weakly polar liquid, such as chloroform or ethyl ether, about 5, while those of highly polar liquids, such as ethanol and water, range from 25 to 80.

Atomic polarization

Solutions and solubilities

The ability of liquids to dissolve solids, other liquids, or gases has long been recognized as one of the fundamental phenomena of nature encountered in daily life. The practical importance of solutions and the need to understand their properties have challenged numerous writers since the Ionian philosophers and Aristotle. Though many physicists and chemists have devoted themselves to a study of solutions, as of the early 1990s it was still an incompletely understood subject under active investigation.

A solution is a mixture of two or more chemically distinct substances that is said to be homogeneous on the molecular scale—the composition at any one point in the mixture is the same as that at any other point. This is in contrast to a suspension (or slurry), in which small discontinuous particles are surrounded by a continuous fluid. Although the word solution is commonly applied to the liquid state of matter, solutions of solids and gases are also possible; brass, for example, is a solution of copper and zinc, and air is a solution primarily of oxygen and nitrogen with a few other gases present in relatively small amounts.

The ability of one substance to dissolve another depends always on the chemical nature of the substances, frequently on the temperature, and occasionally on the pressure. Water, for example, readily dissolves methyl alcohol but does not dissolve mercury; it barely dissolves benzene at room temperature but does so increasingly as the temperature

rises. While the solubility in water of the gases present in air is extremely small at atmospheric pressure, it becomes appreciable at high pressures where, in many cases, the solubility of a gas is (approximately) proportional to its pressure. Thus, a diver breathes air (four-fifths nitrogen) at a pressure corresponding to the pressure around him, and, as he goes deeper, more air dissolves in his blood. If he ascends rapidly, the solubility of the gases decreases so that they leave his blood suddenly, forming bubbles in the blood vessels. This condition (known as the bends) is extremely painful and may cause death; it can be alleviated by breathing, instead of air, a mixture of helium and oxygen because the solubility of helium in blood is much lower than that of nitrogen.

Effects of temperature and pressure

The solubility of one fluid in another may be complete or partial; thus, at room temperature water and methyl alcohol mix in all proportions, but 100 grams of water dissolve only 0.07 gram of benzene. Though it is generally supposed that all gases are completely miscible—*i.e.*, mutually soluble in all proportions—this is true only at normal pressures. At high pressures pairs of chemically unlike gases may exhibit only limited miscibility; for example, at 20° C helium and xenon are completely miscible at pressures below 200 atmospheres but become increasingly immiscible as the pressure rises.

The ability of a liquid to dissolve selectively forms the basis of common separation operations in chemical and related industries. A mixture of two gases, carbon dioxide and nitrogen, can be separated by bringing it into contact with ethanolamine, a liquid solvent that readily dissolves carbon dioxide but barely dissolves nitrogen. In this process, called absorption, the dissolved carbon dioxide is later recovered, and the solvent is made usable again by heating the carbon dioxide-rich solvent, since the solubility of a gas in a liquid usually (but not always) decreases with rising temperature. A similar absorption operation can remove a pollutant such as sulfur dioxide from smokestack gases in a plant using sulfur-containing coal or petroleum as fuel.

The process wherein a dissolved substance is transferred from one liquid to another is called extraction. As an example, phenolic pollutants (organic compounds of the types known as phenol, cresol, and resorcinol) are frequently found in industrial aqueous waste streams, and, since these phenolics are damaging to marine life, it is important to remove them before sending the waste stream back to a lake or river. One such removal technique is to bring the waste stream into contact with a water-insoluble solvent (*e.g.*, an organic liquid such as a high-boiling hydrocarbon) that has a strong affinity for the phenolic pollutant. The solubility of the phenolic in the solvent divided by that in water is called the distribution coefficient, and it is clear that for an efficient extraction process it is desirable to have as large a distribution coefficient as possible.

CLASSES OF SOLUTIONS

Electrolytes and nonelectrolytes. Broadly speaking, liquid mixtures can be classified as either solutions of electrolytes or solutions of nonelectrolytes. Electrolytes are substances that can dissociate into electrically charged particles called ions, while nonelectrolytes consist of molecules that bear no net electric charge. Thus, when ordinary salt (sodium chloride, formula NaCl) is dissolved in water, it forms an electrolytic solution, dissociating into positive sodium ions (Na^+) and negative chloride ions (Cl^-), whereas sugar dissolved in water maintains its molecular integrity and does not dissociate. Because of its omnipresence, water is the most common solvent for electrolytes; the ocean is a solution of electrolytes. Electrolyte solutions, however, are also formed by other solvents (such as ammonia and sulfur dioxide) that have a large dielectric constant (a measure of the ability of a fluid to decrease the forces of attraction and repulsion between charged particles). The energy required to separate an ion pair (*i.e.*, one ion of positive charge and one ion of negative charge) varies inversely with the dielectric constant, and, therefore, appreciable dissociation into separate ions occurs only in solvents with large dielectric constants.

Ion pairs

Most electrolytes (for example, salts) are nonvolatile, which means that they have essentially no tendency to enter the vapour phase. There are, however, some notable exceptions, such as hydrogen chloride (HCl), which is readily soluble in water, where it forms hydrogen ions (H^+) and chloride ions (Cl^-). At normal temperature and pressure, pure hydrogen chloride is a gas, and, in the absence of water or some other ionizing solvent, hydrogen chloride exists in molecular, rather than ionic, form.

Solutions of electrolytes readily conduct electricity, whereas nonelectrolyte solutions do not. A dilute solution of hydrogen chloride in water is a good electrical conductor, but a dilute solution of hydrogen chloride in a hydrocarbon is a good insulator. Because of the large difference in dielectric constants, hydrogen chloride is ionized in water but not in hydrocarbons.

Weak electrolytes. While classification under the heading electrolyte-solution or nonelectrolyte-solution is often useful, some solutions have properties near the boundary between these two broad classes. Although such substances as ordinary salt and hydrogen chloride are strong electrolytes—*i.e.*, they dissociate completely in an ionizing solvent—there are many substances, called weak electrolytes, that dissociate to only a small extent in ionizing solvents. For example, in aqueous solution, acetic acid can dissociate into a positive hydrogen ion and a negative acetate ion (CH_3COO^-), but it does so to a limited extent; in an aqueous solution containing 50 grams acetic acid and 1,000 grams water, less than 1 percent of the acetic acid molecules are dissociated into ions. Therefore, a solution of acetic acid in water exhibits some properties associated with electrolyte solutions (*e.g.*, it is a fair conductor of electricity), but in general terms it is more properly classified as a nonelectrolyte solution. By similar reasoning, an aqueous solution of carbon dioxide is also considered a nonelectrolyte solution even though carbon dioxide and water have a slight tendency to form carbonic acid, which, in turn, dissociates to a small extent to hydrogen ions and bicarbonate ions (HCO_3^-).

Endothermic and exothermic solutions. When two substances mix to form a solution, heat is either evolved (an exothermic process) or absorbed (an endothermic process); only in the special case of an ideal solution do substances mix without any heat effect. Most simple molecules mix with a small endothermic heat of solution, while exothermic heats of solution are observed when the components interact strongly with one another. An extreme example of an exothermic heat of mixing is provided by adding an aqueous solution of sodium hydroxide, a powerful base, to an aqueous solution of hydrogen chloride, a powerful acid; the hydroxide ions (OH^-) of the base combine with the hydrogen ions of the acid to form water, a highly exothermic reaction that yields 75,300 calories per 100 grams of water formed. In nonelectrolyte solutions, heat effects are usually endothermic and much smaller, often about 100 calories, when roughly equal parts are mixed to form 100 grams of mixture.

Volume changes caused by the formation of a solution

Formation of a solution usually is accompanied by a small change in volume. If equal parts of benzene and stannic chloride are mixed, the temperature drops; if the mixture is then heated slightly to bring its temperature back to that of the unmixed liquids, the volume increases by about 2 percent. On the other hand, mixing roughly equal parts of acetone and chloroform produces a small decrease in volume, about 0.2 percent. It frequently happens that mixtures with endothermic heats of mixing expand—*i.e.*, show small increases in volume—while mixtures with exothermic heats of mixing tend to contract.

A large decrease in volume occurs when a gas is dissolved in a liquid. For example, at 0° C and atmospheric pressure, the volume of 28 grams of nitrogen gas is 22,400 cubic centimetres. When these 28 grams of nitrogen are dissolved in an excess of water, the volume of the water increases only 40 cubic centimetres; the decrease in volume accompanying the dissolution of 28 grams of nitrogen in water is therefore 22,360 cubic centimetres. In this case, it is said that the nitrogen gas has been condensed into a liquid, the word condense meaning "to make dense"—*i.e.*, to decrease the volume.

PROPERTIES OF SOLUTIONS

Composition ratios. The composition of a liquid solution means the composition of that solution in the bulk—that is, of that part that is not near the surface. The interface between the liquid solution and some other phase (for example, a gas such as air) has a composition that differs, sometimes very much, from that of the bulk. The environment at an interface is significantly different from that throughout the bulk of the liquid, and in a solution the molecules of a particular component may prefer one environment over the other. If the molecules of one component in the solution prefer to be at the interface as opposed to the bulk, it is said that this component is positively adsorbed at the interface. In aqueous solutions of organic liquids, the organic component is usually positively adsorbed at the solution-air interface; as a result, it is often possible to separate a mixture of an organic solute from water by a process called froth separation. Air is bubbled vigorously into the solution, and a froth is formed. The composition of the froth differs from that of the bulk because the organic solute concentrates at the interfacial region. The froth is mechanically removed and collapsed, and, if further separation is desired, a new froth is generated. The tendency of some dissolved molecules to congregate at the surface has been utilized in water conservation. A certain type of alcohol, when added to water, concentrates at the surface to form a barrier to evaporating water molecules. In warm climates, therefore, water loss by evaporation from lakes can be significantly reduced by introducing a solute that adsorbs positively at the lake-air interface.

The composition of a solution can be expressed in a variety of ways, the simplest of which is the weight fraction, or weight percent; for example, the salt content of seawater is about 3.5 weight percent—*i.e.*, of 100 grams of seawater, 3.5 grams is salt. For a fundamental understanding of solution properties, however, it is often useful to express composition in terms of molecular units such as molecular concentration, molality, or mole fraction. To understand these terms, it is necessary to define atomic and molecular weights. The atomic weight of elements is a relative figure, with one atom of the carbon-12 isotope being assigned the atomic weight of 12; the atomic weight of hydrogen is then approximately 1, of oxygen approximately 16, and the molecular weight of water (H_2O) 18. The atomic and molecular theory of matter asserts that the atomic weight of any element in grams must contain the same number of atoms as the atomic weight in grams (the gram-atomic weight) of any other element. Thus, two grams of molecular hydrogen (H_2)—its gram-molecular weight—contain the same number of molecules as 18 grams of water or 32 grams of oxygen molecules (O_2). Further, a specified volume of any gas (at low pressure) contains the same number of molecules as the same volume of any other gas at the same temperature and pressure. At standard temperature and pressure (0° C and one atmosphere) the volume of one gram-molecular weight of any gas has been determined experimentally to be approximately 22.4 litres (23.7 quarts). The number of molecules in this volume of gas, or in the gram-molecular weight of any compound, is called Avogadro's number.

Role of atomic weight

Molarity. Molecular concentration is the number of molecules of a particular component per unit volume. Since the number of molecules in a litre or even a cubic centimetre is enormous, it has become common practice to use what are called molar, rather than molecular, quantities. A mole is the gram-molecular weight of a substance and, therefore, also Avogadro's number of molecules (6.02×10^{23}). Thus, the number of moles in a sample is the weight of the sample divided by the molecular weight of the substance; it is also the number of molecules in the sample divided by Avogadro's number. Instead of using molecular concentration, it is more convenient to use molar concentration; instead of saying, for example, that the concentration is 12.04×10^{23} molecules per litre, it is simpler to say that it is two moles per litre. Concentration in moles per litre (*i.e.*, molarity) is usually designated by the letter M.

Molality. In electrolyte solutions it is common to distinguish between the solvent (usually water) and the dissolved substance, or solute, which dissociates into ions. For these solutions it is useful to express composition in terms of molality, designated as m, a unit proportional to the number of undissociated solute molecules (or, alternatively, to the number of ions) per 1,000 grams of solvent. The number of molecules or ions in 1,000 grams of solvent usually is very large, so molality is defined as the number of moles per 1,000 grams of solvent.

Formality. Many compounds do not exist in molecular form, either as pure substances or in their solutions. The particles that make up sodium chloride (NaCl), for example, are sodium ions (Na^+) and chloride ions (Cl^-), and, although equal numbers of these two ions are present in any sample of sodium chloride, no Na^+ ion is associated with a particular Cl^- ion to form a neutral molecule having the composition implied by the formula. Therefore, even though the compositions of such compounds are well defined, it would be erroneous to express concentrations of their solutions in terms of molecular weights. A useful concept in cases of this kind is that of the formula weight, defined as the sum of the weights of the atoms in the formula of the compound; thus, the formula weight of sodium chloride is the sum of the atomic weights of sodium and chlorine, 23 plus 35.5, or 58.5, and a solution containing 58.5 grams of sodium chloride per litre is said to have a concentration of one formal, or 1 F.

Formula weight

Mole fraction and mole percentage. It often is useful to express the composition of nonelectrolyte solutions in terms of mole fraction or mole percentage. In a binary mixture—*i.e.*, a mixture of two components, 1 and 2—there are two mole fractions, x_1 and x_2, which satisfy the relation $x_1 + x_2 = 1$. The mole fraction x_1 is the fraction of molecules of species 1 in the solution, and x_2 is the fraction of molecules of species 2 in the solution. (Mole percentage is the mole fraction multiplied by 100.)

Volume fraction. The composition of a nonelectrolyte solution containing very large molecules, known as polymers, is most conveniently expressed by the volume fraction (Φ)—*i.e.*, the volume of polymer used to prepare the solution divided by the sum of that volume of polymer and the volume of the solvent.

Equilibrium properties. A quantitative description of liquid-solution properties when the system is in equilibrium is provided by relating the vapour pressure of the solution to its composition. The vapour pressure of a liquid, pure or mixed, is the pressure exerted by those molecules that escape from the liquid to form a separate vapour phase above the liquid. If a quantity of liquid is placed in an evacuated, closed container the volume of which is slightly larger than that of the liquid, most of the container is filled with the liquid, but, immediately above the liquid surface, a vapour phase forms, consisting of molecules that have passed through the liquid surface from liquid to gas; the pressure exerted by that vapour phase is called the vapour (or saturation) pressure. For a pure liquid, this pressure depends only on the temperature, the best-known example being the normal boiling point, which is that temperature at which the vapour pressure is equal to the pressure of the atmosphere. Figure 39 shows vapour pressures for a few common liquids. The vapour pressure is one atmosphere at 100° C for water, at 78.5° C for ethyl alcohol, and at 125.7° C for octane. In a liquid solution, the component with the higher vapour pressure is called the light component, and that with the lower vapour pressure is called the heavy component.

Vapour pressure

In a liquid mixture, the vapour pressure depends not only on the temperature but also on the composition, and the key problem in understanding the properties of solutions lies in determining this composition dependence. The simplest approximation is to assume that, at constant temperature, the vapour pressure of a solution is a linear function of its composition (*i.e.*, as one increases, so does the other in such proportion that, when the values are plotted, the resulting graph is a straight line). A mixture following this approximation is called an ideal solution.

Fugacity. In a pure liquid, the vapour generated by its escaping molecules necessarily has the same composition as that of the liquid. In a mixture, however, the compo-

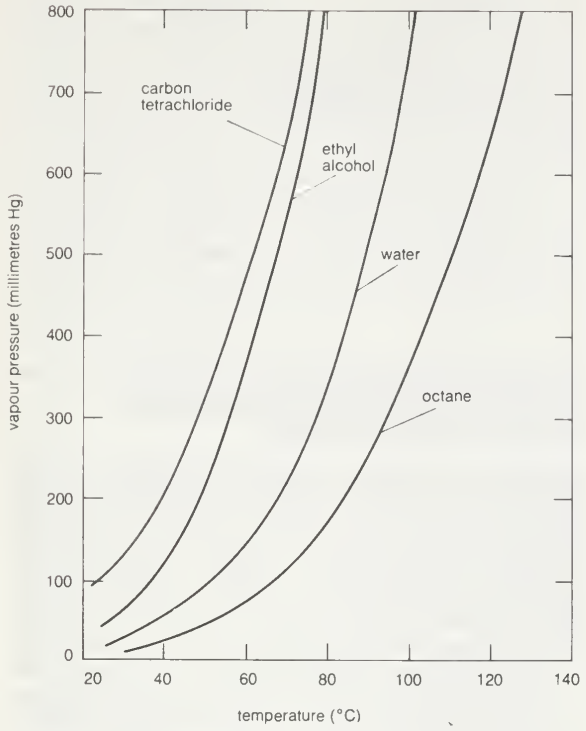

Figure 39: Vapour pressures of several pure liquids.

sition of the vapour is not the same as that of the liquid; the vapour is richer in that component whose molecules have greater tendency to escape from the liquid phase. This tendency is measured by fugacity, a term derived from the Latin *fugere* ("to escape, to fly away"). The fugacity of a component in a mixture is (essentially) the pressure that the component exerts in the vapour phase when the vapour is in equilibrium with the liquid mixture. (A state of equilibrium is attained when all the properties remain constant in time and there is no net transfer of energy or matter between the vapour and the liquid.) If the vapour phase can be considered to be an ideal gas (*i.e.*, the molecules in the gas phase are assumed to act independently and without any influence on each other), then the fugacity of a component, i, is equal to its partial pressure, which is defined as the product of the total vapour pressure, P, and the vapour-phase mole fraction, y_i. Assuming ideal gas behaviour for the vapour phase, the fugacity (y_iP) equals the product of the liquid-phase mole fraction, x_i, the vapour pressure of pure liquid at the same temperature as that of the mixture, $P_i°$, and the activity coefficient, γ_i. The real concentration of a substance may not be an accurate measure of its effectiveness, because of physical and chemical interactions, in which case an effective concentration must be used, called the activity. The activity is given by the product of the mole fraction x_i and the activity coefficient γ_i. The equation is:

The activity coefficient

$$y_iP = \gamma_i x_i P_i°. \qquad (4)$$

Raoult's law. In a real solution, the activity coefficient, γ_i, depends on both temperature and composition, but, in an ideal solution, γ_i equals 1 for all components in the mixture. For an ideal binary mixture then, the above equation becomes, for components 1 and 2, $y_1P = x_1P_1°$ and $y_2P = x_2P_2°$, respectively. Upon adding these equations—recalling that $x_1 + x_2 = 1$ and $y_1 + y_2 = 1$—the total pressure, P, is shown to be expressed by the equation $P = x_1P_1° + x_2P_2° = x_1[P_1° - P_2°] + P_2°$, which is a linear function of x_1.

Assuming $\gamma_1 = \gamma_2 = 1$, equations for y_1P and y_2P express what is commonly known as Raoult's law, which states that at constant temperature the partial pressure of a component in a liquid mixture is proportional to its mole fraction in that mixture (*i.e.*, each component exerts a pressure that depends directly on the number of its molecules present). It is unfortunate that the word law is associated with this relation, because only very few mixtures behave according to the equations for ideal binary mixtures. In most cases the activity coefficient, γ_i, is not equal to unity. When γ_i is greater than 1, there are positive deviations from Raoult's law; when γ_i is less than 1, there are negative deviations from Raoult's law.

An example of a binary system that exhibits positive deviations from Raoult's law is represented in Figure 40, the partial pressures and the total pressure being related to the liquid-phase composition; if Raoult's law were valid, all the lines would be straight, as indicated by the dashed lines. As a practical result of these relationships, it is often possible by a series of repeated vaporizations and condensations to separate a liquid mixture into its components, a sequence of steps called fractional distillation.

Azeotropic mixtures

When the vapour in equilibrium with a liquid mixture has a composition identical to that of the liquid, the mixture is called an azeotrope. It is not possible to separate an azeotropic mixture by fractional distillation because no change in composition is achieved by a series of vaporizations and condensations. Azeotropic mixtures are common. At the azeotropic composition, the total pressure (at constant temperature) is always either a maximum or a minimum with respect to composition, and the boiling temperature (at constant pressure) is always either a minimum or a maximum temperature.

Partial miscibility. Only pairs of liquids that are completely miscible have been considered so far. Many pairs of liquids, however, are only partially miscible in one another, the degree of miscibility often depending strongly on temperature. In most cases, rising temperature produces enhanced solubility, but this is not always so. For example, at 50° C the solubility (weight percent) of *n*-butyl alcohol in water is 6.5 percent, whereas that of water in *n*-butyl alcohol is 22.4 percent. At 127° C, the upper consolute temperature, complete miscibility is attained: above 127° C the two liquids mix in all proportions, but below 127° C they show a miscibility gap. Thus, if *n*-butyl alcohol is added to water at 50° C, there is only one liquid phase until 6.5 weight percent of the mixture is alcohol; when more alcohol is added, a second liquid phase appears the composition of which is 22.4 weight percent water. When sufficient alcohol is present to make the overall compo-

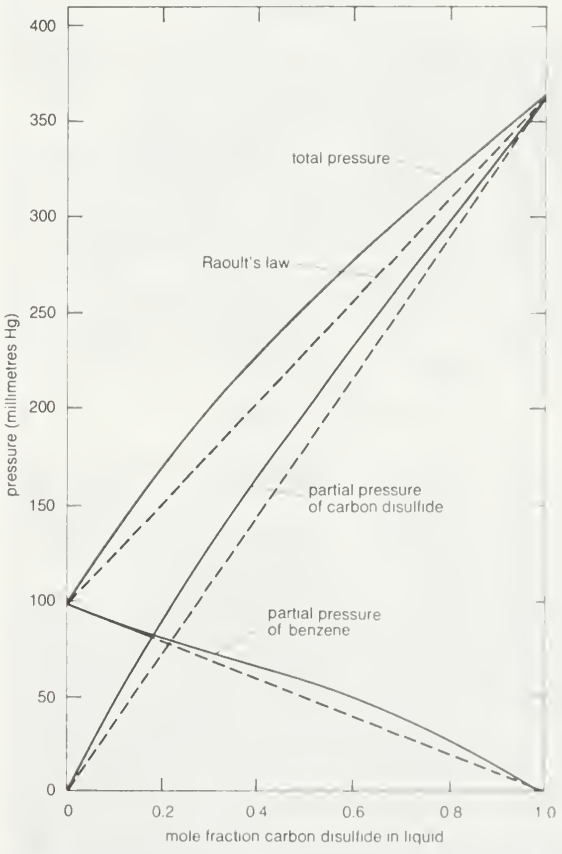

Figure 40: Total pressure and partial pressures for the system benzene–carbon disulfide at 25 C (see text).

sition 77.6 weight percent alcohol, the first phase disappears, and only one liquid phase remains. A qualitatively different example is the system water-triethylamine, which has a lower consolute temperature at 17° C. Below 17° C the two liquids are completely miscible, but at higher temperatures they are only partially miscible. Finally, it is possible, although rare, for a binary system to exhibit both upper and lower consolute temperatures. Above 128° C and below 49° C butyl glycol and water are completely miscible, but between these temperatures they do not mix in all proportions.

Colligative properties. Colligative properties depend only on the concentration of the solute, not on the identity of the solute molecules. The concept of an ideal solution, as expressed by Raoult's law, was already well-known during the last quarter of the 19th century, and it provided the early physical chemists with a powerful technique for measuring molecular weights. (Reliable measurements of molecular weights, in turn, provided important evidence for the modern atomic and molecular theory of matter.)

Rise in boiling point. It was observed that, whenever one component in a binary solution is present in large excess, the partial pressure of that component is correctly predicted by Raoult's law, even though the solution may exhibit departures from ideal behaviour in other respects. When Raoult's law is applied to the solvent of a very dilute solution containing a nonvolatile solute, it is possible to calculate the mole fraction of the solute from an experimental determination of the rise in boiling point that results when the solute is dissolved in the solvent. Since the separate weights of solute and solvent are readily measured, the procedure provides a simple experimental method for the determination of molecular weight. If a weighed amount of a nonvolatile substance, w_2, is dissolved in a weighed amount of a solvent, w_1, at constant pressure, the increase in the boiling temperature, ΔT_{b1}, the gas constant, R (derived from the gas laws), the heat of vaporization of the pure solvent per unit weight, l_1^{vap}, and the boiling temperature of pure solvent, T_{b1}, are related in a simple product of ratios equal to the molecular weight of the solute, M_2. The equation is:

$$M_2 = \left(\frac{RT_{b1}^2}{l_1^{\text{vap}}}\right)\left(\frac{w_2}{w_1}\right)\left(\frac{1}{\Delta T_{b1}}\right). \qquad (5)$$

The essence of this technique follows from the observation that, in a dilute solution of a nonvolatile solute, the rise in boiling point is proportional to the number of solute molecules, regardless of their size and mass.

Decrease in freezing point. Another colligative property of solutions is the decrease in the freezing temperature of a solvent that is observed when a small amount of solute is dissolved in that solvent. By reasoning similar to that leading to equation (5), the freezing-point depression, ΔT_f, the freezing temperature of pure solvent, T_{f1}, the heat of fusion (also called the heat of melting) of pure solvent per unit weight, l_1^{fusion}, and the weights of solute and solvent in the solution, w_2 and w_1, respectively, are so related as to equal the molecular weight of solute, M_2, in the equation

$$M_2 = \left(\frac{RT_{f1}^2}{l_1^{\text{fusion}}}\right)\left(\frac{w_2}{w_1}\right)\left(\frac{1}{\Delta T_f}\right). \qquad (6)$$

A well-known practical application of freezing-point depression is provided by adding antifreeze to the cooling water in an automobile's radiator. Water alone freezes at 0° C, but the freezing temperature decreases appreciably when ethylene glycol is mixed with water.

Osmotic pressure. A third colligative property, osmotic pressure, helped to establish the fundamentals of modern physical chemistry and played a particularly important role in the early days of solution theory. Osmosis is especially important in medicine and biology, but in recent years it has also been applied industrially to problems such as the concentration of fruit juices, the desalting of seawater, and the purification of municipal sewage. Osmosis occurs whenever a liquid solution is in contact with a semipermeable membrane—*i.e.*, a thin, porous wall whose porosity is such that some, but not all, of the components in the liquid mixture can pass through the wall. A semipermeable membrane is a selective barrier, and many

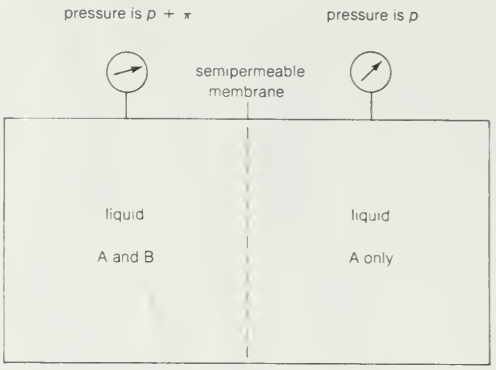

Figure 41: Osmotic pressure π caused by a membrane that allows A to pass but not B. A representative system could consist of water (A) and salt (B).

such barriers are found in plants and animals. Osmosis gives rise to what is known as osmotic pressure, as illustrated in Figure 41, which shows a container at uniform temperature divided into two parts by a semipermeable membrane that allows only molecules of component A to pass from the left to the right side; the selective membrane does not allow molecules of component B to pass. Example compounds for A and B might be water and sodium chloride (table salt), respectively. Molecules of component A are free to pass back and forth through the membrane, but, at equilibrium, when the fugacity (escaping tendency) of A in the right-hand side is the same as that in the left-hand side, there is no net transfer of A from one side to the other. On the left side, the presence of B molecules lowers the fugacity of A, and, therefore, to achieve equal fugacities for A on both sides, some compensating effect is needed on the left side. This compensating effect is an enhanced pressure, designated by π and called osmotic pressure. At equilibrium the pressure in the left side of the container is larger than that in the right side; the difference in pressure is π. In the simplest case, when the concentration of B is small (*i.e.*, A is in excess), the osmotic pressure is the product of the gas constant (R), the absolute temperature (T), and the concentration of B (c_B) in the solution expressed in moles of B per unit volume: $\pi = RTc_B$. Since the osmotic pressure for a dilute solution is proportional to the number of solute molecules, it is a colligative property, and, as a result, osmotic-pressure measurements are often used to determine molecular weights, especially for large molecules such as polymers. When w_B grams of solute B are added to a large amount of solvent A at temperature T, and V is the volume of liquid solvent A in the left side of the container, then the molecular weight of B, M_B, is given by

Osmotic equilibrium

$$M_B = \frac{w_B RT}{\pi V}. \qquad (7)$$

For sodium chloride in water, c_B is the concentration of the ions, which is twice the concentration of the salt owing to the dissociation of the salt (NaCl) into sodium ions (Na^+) and chloride ions (Cl^-). Thus, for a 3.5 percent sodium chloride solution at 25° C, π is 29 atmospheres, which is the minimum pressure at which a desalination reverse osmosis process can operate.

Transport properties in solutions. Pure fluids have two transport properties that are of primary importance: viscosity and thermal conductivity. Transport properties differ from equilibrium properties in that they reflect not what happens at equilibrium but the speed at which equilibrium is attained. In solutions these two transport properties are also important. In addition, there is a third one, called diffusivity.

Viscosity. The viscosity of a fluid (pure or not) is a measure of its ability to resist deformation. If water is poured into a thin vertical tube with a funnel at the top, it flows easily through the tube, but salad oil is difficult to force into the tube. If the oil is heated, however, its flow through the tube is much facilitated. The intrinsic property that is responsible for these phenomena is the viscosity (the "thickness") of the fluid, a property which is often

strongly affected by temperature. All fluids (liquid or gas) exhibit viscous behaviour (*i.e.*, all fluids resist deformation to some degree), but the range of viscosity is enormous: the viscosity of air is extremely small, while that of glass is essentially infinite. The viscosity of a solution depends not only on temperature but also on composition. By varying the composition of a petroleum mixture, it is possible to attain a desired viscosity at a particular temperature. This is precisely what the oil companies do when they sell oil to a motorist: in winter, they recommend an oil with lower viscosity than that used in summer, because otherwise, on a cold morning, the viscosity of the lubricating oil may be so high that the car's battery will not be powerful enough to move the lubricated piston.

Thermal conductivity. The thermal conductivity of a material reflects its ability to transfer heat by conduction. In practical situations both viscosity and thermal conductivity are important, as is illustrated by the contrast between an air mattress and a water bed. Because of its low viscosity, air yields rapidly to an imposed load, and thus the air mattress responds quickly when someone lying on it changes position. Water, because of its higher viscosity, noticeably resists deformation, and someone lying on a water bed experiences a caressing response whenever position is changed. At the same time, since the thermal conductivity as well as the viscosity of water are larger than those of air, the user of a water bed rapidly gets cold unless a heater keeps the water warm. No heater is required by the user of an air mattress because stagnant air is inefficient in removing heat from a warm body.

Composition and temperature affect the thermal conductivity of a solution but, in typical liquid mixtures, the effect on viscosity is much larger than that on thermal conductivity.

Diffusivity. While viscosity is concerned with the transfer of momentum and thermal conductivity with the transfer of heat, diffusivity is concerned with the transport of molecules in a mixture. If a lump of sugar is put into a cup of coffee, the sugar molecules travel from the surface of the lump into the coffee at a speed determined by the temperature and by the pertinent intermolecular forces. The characteristic property that determines this speed is called diffusivity—*i.e.*, the ability of a molecule to diffuse through a sea of other molecules. Diffusivities in solids are extremely small, and those in liquids are much smaller than those in gases. For this reason, a spoon is used to stir the coffee to speed up the motion of the sugar molecules, but, if the odour of cigarette smoke fills a room, little effort is needed to clear the air—opening the windows for a few minutes is sufficient.

In order to define diffusivity, it is necessary to consider a binary fluid mixture in which the concentration of solute molecules is c_1 at position 1 and c_2 at position 2, which is l centimetres from position 1; if c_1 is larger than c_2, then the concentration gradient (change with respect to distance), given by $(c_2 - c_1)/l$, is a negative number, indicating that molecules of solute spontaneously diffuse from position 1 to position 2. The number of solute molecules that pass through an area of one square centimetre perpendicular to l, per second, is called the flux J (expressed in molecules per second per square centimetre). The diffusivity D is given by the formula

Flux

$$D = -\frac{J}{(c_2 - c_1)/l}. \tag{8}$$

The leading minus sign is introduced because, when the gradient is positive, J is negative, and, by convention, D is a positive number. In binary gaseous mixtures, diffusivity depends only weakly on the composition, and, therefore, to a good approximation, the diffusivity of gas A in gas B is the same as that of gas B in gas A. In liquid systems, however, the diffusivity of solute A in solvent B may be significantly different from that of solute B in solvent A. In a very viscous fluid, molecules cannot rapidly move from one place to another. Therefore, in liquid systems, the diffusivity of solute A depends strongly on the viscosity of solvent B and vice versa. While the letter D is always used for diffusivity, viscosity is commonly given the symbol η; in many liquid solutions it is observed that, as the composition changes (as long as the temperature remains constant), the product $D\eta$ remains nearly the same.

THERMODYNAMICS AND INTERMOLECULAR FORCES IN SOLUTIONS

The properties of solutions depend, essentially, on two characteristics: first, the manner in which the molecules arrange themselves (that is, the geometric array in which the molecules occupy space) and, second, the nature and strength of the forces operating between the molecules.

Energy considerations. The first characteristic is reflected primarily in the thermodynamic quantity S, called entropy, which is a measure of disorder, and the second characteristic is reflected in the thermodynamic quantity H, called enthalpy, which is a measure of potential energy—*i.e.*, the energy that must be supplied to separate all the molecules from one another. Enthalpy minus the product of the absolute temperature T and entropy equals a thermodynamic quantity G, called Gibbs energy (also called free energy):

Enthalpy

$$G = H - TS. \tag{9}$$

From the second law of thermodynamics, it can be shown that, at constant temperature and pressure, any spontaneous process is accompanied by a decrease in Gibbs energy. The change in G that results from mixing is designated by ΔG, which, in turn, is related to changes in H and S at constant temperature by the equation

$$\Delta G = \Delta H - T\Delta S. \tag{10}$$

At a fixed temperature and pressure, two substances mix spontaneously whenever ΔG is negative; that is, mixing (either partial or complete) occurs whenever the Gibbs energy of the substances after mixing is less than that before mixing.

The two characteristics that determine solution behaviour, structure and intermolecular forces, are, unfortunately, not independent, because the structure is influenced by the intermolecular forces and because the potential energy of the mixture depends on the structure. Only in limiting cases is it possible, on the one hand, to calculate ΔS (the entropy change upon mixing) from structural considerations alone and, on the other, to calculate ΔH (the enthalpy change of mixing) exclusively from relations describing intermolecular forces. Nevertheless, such calculations have proved to be useful for establishing models that approximate solution behaviour and that serve as guides in interpreting experimental measurements. Solutions for which structural considerations are dominant are called athermal solutions, and those for which the effects of intermolecular forces are more important than those of structure are called regular solutions (see below *Theories of solutions: Solutions of nonelectrolytes: Regular solutions* and *Athermal solutions*).

Effects of molecular structure. A variety of forces operate between molecules, and there is a qualitative relation between the properties of a solution and the types of intermolecular forces that operate within it. The volume occupied by a solution is determined primarily by repulsive forces. When two molecules are extremely close to one another, they must necessarily exert a repulsive force on each other since two molecules of finite dimensions cannot occupy the same space; two molecules in very close proximity resist attempts to shorten the distance between them.

At larger distances of separation, molecules may attract or repel each other depending on the sign (plus or minus) and distribution of their electrical charge. Two ions attract one another if the charge on one is positive and that on the other is negative; they repel when both carry charges of the same sign. Forces between ions are called Coulomb forces and are characterized by their long range; the force (F) between two ions is inversely proportional to the square of the distance between them; *i.e.*, F varies as $1/r^2$. Noncoulombic physical forces between molecules decay more rapidly with distance; *i.e.*, in general F varies as $1/r^n$, n being larger than 2 for intermolecular forces other than those between ions.

The Coulomb force (F) equals the product of the magnitude of the charge on one ion (e_1) and that on the other

(e_2) divided by the product of the distance squared (r^2) and the dielectric constant (ε):

$$F = \frac{e_1 e_2}{r^2 \varepsilon}. \qquad (11)$$

If both e_1 and e_2 are positive, F is positive and the force is repulsive. If either e_1 or e_2 is positive while the other is negative, F is negative and the force is attractive. Coulomb forces are dominant in electrolyte solutions.

Molecular structure and charge distribution. If a molecule has no net electrical charge, its negative charge is equal to its positive charge. The forces experienced by such molecules depend on how the positive and negative charges are arranged in space. If the arrangement is spherically symmetric, the molecule is said to be nonpolar; if there is an excess of positive charge on one end of the molecule and an excess of negative charge on the other, the molecule has a dipole moment (*i.e.*, a measurable tendency to rotate in an electric or magnetic field) and is therefore called polar. The dipole moment (μ) is defined as the product of the magnitude of the charge, e, and the distance separating the positive and negative charges, l: $\mu = el$. Electrical charge is measured in electrostatic units (esu), and the typical charge at one end of a molecule is of the order of 10^{-10} esu; the distance between charges is of the order of 10^{-8} centimetres (cm). Dipole moments, therefore, usually are measured in debyes (one debye is 10^{-18} esu-cm). For nonpolar molecules, $\mu = 0$.

Dipole moment

Polar molecules. The force F between two polar molecules is directly proportional to the product of the two dipole moments (μ_1 and μ_2) and inversely proportional to the fourth power of the distance between them (r^4): that is, F varies as $\mu_1\mu_2/r^4$. The equation for this relationship contains a constant of proportionality ($F = k\mu_1\mu_2/r^4$), the sign and magnitude of which depend on the mutual orientation of the two dipoles; if the positive end of one faces the negative end of the other, the constant of proportionality is negative (meaning that an attractive force exists), while it is positive (meaning that a repulsive force exists) when the positive end of one faces the positive end of the other. When polar molecules are free to rotate, they tend to favour those orientations that lead to attractive forces. To a first approximation, the force (averaged over all orientations) is inversely proportional to the temperature and to the seventh power of the distance of separation. Mixtures of polar molecules often exhibit only mild deviations from ideality, but mixtures containing polar and nonpolar molecules are frequently strongly nonideal. Because of the qualitative and quantitative differences in intermolecular forces, the molecules segregate: the polar molecules prefer to be with each other, and so do the nonpolar ones. Only at higher temperatures, such that the thermal energy of the molecules offsets the cohesion between identical molecules, do the two liquids mix in all proportions. In mixtures containing both polar and nonpolar components, deviations from Raoult's law diminish as temperature rises.

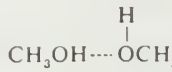
Nonpolar molecules. A nonpolar molecule is one whose charge distribution is spherically symmetric when averaged over time; since the charges oscillate, a temporary dipole moment exists at any given instant in a so-called nonpolar molecule. These temporary dipole moments fluctuate rapidly in magnitude and direction, giving rise to intermolecular forces of attraction called London (or dispersion) forces. All molecules, charged or not, polar or not, interact by London forces. To a first approximation, the London force between two molecules is inversely proportional to the seventh power of the distance of separation; it is therefore short-range, decreasing rapidly as one molecule moves away from the other. The London theory indicates that for simple molecules positive deviations from Raoult's law may be expected (*i.e.*, the activity coefficient γ_i is greater than 1, as explained previously). Since the London theory suggests that the attractive forces between unlike simple molecules are smaller than those corresponding to an ideal solution, the escaping tendency of the molecules in solution is larger than that calculated by Raoult's law. As a result, mixing of small nonpolar molecules is endothermic (absorbing heat from the surroundings) and the volume occupied by the liquid solution often exceeds that of the unmixed components—that is, the components expand on mixing.

London forces

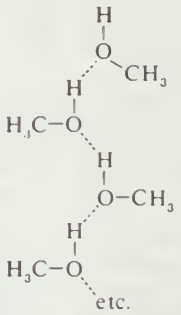
In addition to the forces listed above, there are so-called induction forces set up when a charged or polar molecule induces a dipole in another molecule: the electric field of the inducing molecule distorts the charge distribution in the other. When a charged molecule induces a dipole in another, the force is always attractive and is inversely proportional to the fifth power of the distance of separation. When a polar molecule induces a dipole in another molecule, the force is also attractive and is inversely proportional to the seventh power of separation. Induction forces are usually small but may make a significant contribution to the energy of a mixture of molecules that are strongly dissimilar.

Effects of chemical interactions. In many cases the properties of a mixture are determined primarily by forces that are more properly classified as chemical rather than as physical. For example, when dinitrogen pentoxide is dissolved in water, a new substance, nitric acid, is formed; and it is necessary to interpret the behaviour of such a solution in terms of its chemical properties, which, in this case, are more important than its physical properties. This example is an extreme one, and there are many solutions for which the chemical effect is less severe but nevertheless dominant.

Hydrogen bonding: association. This dominance is especially important in those solutions that involve hydrogen bonding. Whenever a solution contains molecules with an electropositive hydrogen atom and with an electronegative atom (such as nitrogen, oxygen, sulfur, or fluorine), hydrogen bonding may occur and, when it does, the properties of the solution are affected profoundly. Hydrogen bonds may form between identical molecules or between dissimilar molecules; for example, methanol (CH_3OH) has an electropositive (electron-attracting) hydrogen atom and also an electronegative (electron-donating) oxygen atom, and therefore two methanol molecules may hydrogen-bond (represented by the dashed line) singly to form the structure



or in chains to form



Hydrogen bonding between identical molecules is often called association.

Hydrogen bonding: solvation. In a mixture of methanol and, say, pyridine (C_5H_5N), hydrogen bonds can also form between the electropositive hydrogen atom in methanol and the electronegative nitrogen atom in pyridine. Hydrogen bonding between dissimilar molecules is an example of a type of interaction known as solvation. Since the extent of association or solvation or both depends on the concentrations of the solution's components, the partial pressure of a component is not even approximately proportional to its mole fraction as given by Raoult's law; therefore, large deviations from Raoult's law are commonly observed in solutions in which hydrogen bonding is extensive. Broadly speaking, association of one component, but not the other, tends to produce positive deviations from Raoult's law, because the associating component hydrogen-bonds to a smaller extent when it is surrounded by other molecules than it does in the pure state. On the other hand, solvation

Deviations from Raoult's law

between dissimilar molecules tends to produce negative deviations from Raoult's law.

THEORIES OF SOLUTIONS

Solutions of nonelectrolytes. *Activity coefficients and excess functions.* As has been explained previously, when actual concentrations do not give simple linear relations for the behaviour of a solution, activity coefficients, symbolized by γ_i, are used in expressing deviations from Raoult's law. Activity coefficients are directly related to excess functions, and, in attempting to understand solution behaviour, it is convenient to characterize nonelectrolyte solutions in terms of these functions. In particular, it is useful to distinguish between two types of limiting behaviour: one corresponds to that of a regular solution; the other, to that of an athermal solution (*i.e.*, when components are mixed, no heat is generated or absorbed).

In a binary mixture with mole fractions x_1 and x_2 and activity coefficients γ_1 and γ_2, these quantities can be related to a thermodynamic function designated by G^E, called the excess Gibbs (or free) energy. The significance of the word excess lies in the fact that G^E is the Gibbs energy of a solution in excess of what it would be if it were ideal.

In a binary solution the two activity coefficients are not independent but are related by an exact differential equation called the Gibbs-Duhem relation. If experimental data at constant temperature are available for γ_1 and γ_2 as a function of composition, it is possible to apply this equation to check the data for thermodynamic consistency: the data are said to be consistent only if they satisfy the Gibbs-Duhem relation. Experimental data that do not satisfy this relation are thermodynamically inconsistent and therefore must be erroneous.

To establish a theory of solutions, it is necessary to construct a theoretical (or semitheoretical) equation for the excess Gibbs energy as a function of absolute temperature (T) and the mole fractions x_1 and x_2. After such an equation has been established, the individual activity coefficients can readily be calculated.

Gibbs energy, by definition, consists of two parts: one part is the enthalpy, which reflects the intermolecular forces between the molecules, which, in turn, are responsible for the heat effects that accompany the mixing process (enthalpy is, in a general sense, a measure of the heat content of a substance); and the other part is the entropy, which reflects the state of disorder (a measure of the random behaviour of particles) in the mixture. The excess Gibbs energy G^E is given by the equation

$$G^E = H^E - TS^E, \tag{12}$$

where H^E is the excess enthalpy and S^E is the excess entropy. The word excess means in excess of that which would prevail if the solution were ideal. In the simplest case, both H^E and S^E are zero; in that case the solution is ideal and $\gamma_1 = \gamma_2 = 1$. In the general case, neither H^E nor S^E is zero, but two types of semi-ideal solutions can be designated: in the first, S^E is zero but H^E is not; this is called a regular solution. In the second, H^E is zero but S^E is not; this is called an athermal solution. An ideal solution is both regular and athermal.

Types of semi-ideal solutions

Regular solutions. The word regular implies that the molecules mix in a completely random manner, which means that there is no segregation or preference; a given molecule chooses its neighbours with no regard for chemical identity (species 1 or 2). In a regular solution of composition x_1 and x_2, the probability that the neighbour of a given molecule is of species 1 is given by the mole fraction x_1, and the probability that it is of species 2 is given by x_2.

Two liquids form a solution that is approximately regular when the molecules of the two liquids do not differ appreciably in size and there are no strong orienting forces caused by dipoles or hydrogen bonding. In that event, the mixing process can be represented by the lattice model shown in Figure 42; the left half of the diagram shows pure liquids 1 and 2, and the right half shows the mixture obtained when the central molecule of liquid 1 is interchanged with the central molecule of liquid 2. Before interchange, the potential energy between central molecule 1 and one of its immediate neighbours is Γ_{11}, and that between central molecule 2 and one of its immediate neighbours is Γ_{22}. After interchange, the potential energy between molecule 1 and one of its immediate neighbours is Γ_{12}, and that between molecule 2 and one of its immediate neighbours is also Γ_{12}. The change in energy that accompanies this mixing process is equal to twice the interchange energy (ω), which is equal to the potential energy after mixing less one-half the sum of the potential energies before mixing, the whole multiplied by the number of immediate neighbours, called the coordination number (z), surrounding the two shifted molecules:

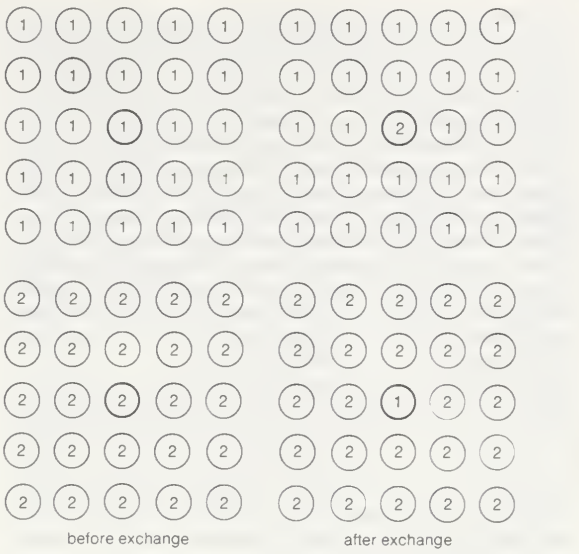


Figure 42: Physical significance of interchange energy. The energy absorbed in the process above is 2ω (see text).

$$\omega = z[\Gamma_{12} - \frac{1}{2}(\Gamma_{11} + \Gamma_{22})]. \tag{13}$$

In the two-dimensional representation (Figure 42), z equals 4; but, in three dimensions, z varies between 6 and 12, depending on the lattice geometry. In this simple lattice model, the interchange process occurs without change of volume; thus, in this particular case, the excess enthalpy is the same as the energy change upon mixing. Assuming regular-solution behaviour (*i.e.*, $S^E = 0$), an equation may be derived relating Gibbs energy, Avogadro's number, interchange energy, and mole fractions. In principle, the interchange energy (ω) may be positive or negative, but, for simple molecules, for which only London forces of attraction are important, ω is positive. The equation obtained from the simple lattice model can be extended semiempirically to apply to mixtures of molecules whose sizes are not nearly the same by using volume fractions instead of mole fractions to express the effect of composition and by introducing the concept of cohesive energy density, which is defined as the potential energy of a liquid divided by its volume. The adjective cohesive is well chosen because it indicates that this energy is associated with the forces that keep the molecules close together in a condensed state. Again restricting attention to nonpolar molecules and assuming a completely random mixture ($S^E = 0$), an equation may be derived that requires only pure-component properties to predict the excess Gibbs energy (and hence the activity coefficients) of binary mixtures. Because of many simplifying assumptions, this equation does not give consistently accurate results, but in many cases it provides good semiquantitative estimates. The form of the equation is such that the excess Gibbs energy is larger than zero; hence, the equation is not applicable to mixtures that have negative deviations from Raoult's law.

Cohesive energy density

Athermal solutions. In a solution in which the molecules of one component are much larger than those of the other, the assumption that the solution is regular (*i.e.*, that $S^E = 0$) no longer provides a reasonable approximation even if the effect of intermolecular forces is neglected. A large flexible molecule (*e.g.*, a chain molecule such as polyethylene) can attain many more configurations when

it is surrounded by small molecules than it can when surrounded by other large flexible molecules; the state of disorder in such a solution is therefore much larger than that of a regular solution in which $S^E = 0$. A solution of very large molecules (*i.e.*, polymers) in an ordinary liquid solvent is analogous to a mixture of cooked spaghetti (representing the polymers) and tomato sauce (the solvent). When there is a large amount of sauce and relatively little spaghetti, each piece of spaghetti is free to exist in many different shapes; this freedom, however, becomes restricted as the number of spaghetti pieces rises and the amount of sauce available for each strand declines. The excess entropy then is determined primarily by the freedom that the spaghetti has in the tomato sauce mixture relative to the freedom it has in the absence of sauce.

Regular solutions and athermal solutions represent limiting cases; real solutions are neither regular nor athermal. For real solutions it has been proposed to calculate G^E by combining the equations derived separately for regular solutions and for athermal solutions, but, in view of the restrictive and mutually inconsistent assumptions that were made in deriving these two equations, the proposal has met with only limited success.

Associated and solvated solutions. For those solutions in which there are strong intermolecular forces due to large dipole moments, hydrogen bonding, or complex formation, equations based on fundamental molecular theory cannot be applied, but it is frequently useful to apply a chemical treatment—*i.e.*, to describe the liquid mixture in terms of association and solvation, by assuming the existence of a variety of distinct chemical species in chemical equilibrium with one another. For example, there is much experimental evidence for association in acetic acid, in which most of the molecules dimerize; *i.e.*, two single acetic acid molecules, called monomers, combine to form a new molecule, called a dimer, through hydrogen bonding. When acetic acid is dissolved in a solvent such as benzene, the extent of dimerization of acetic acid depends on the temperature and on the total concentration of acetic acid in the solution. The escaping tendency (vapour pressure) of a monomer is much greater than that of a dimer, and it is thus possible to explain the variation of activity coefficient with composition for acetic acid in benzene; the activity coefficient of acetic acid in an excess of benzene is large because, under these conditions, acetic acid is primarily in the monomeric state, whereas pure acetic acid is almost completely dimerized. In the acetic acid–benzene system, association of acetic acid molecules produces positive deviations from Raoult's law.

Solvation

When a solvent and a solute molecule link together with weak bonds, the process is called solvation. For example, in the system acetone-chloroform, a hydrogen bond is formed between the hydrogen atom in chloroform and the oxygen atom in acetone. In this case, hydrogen bonding depresses the escaping tendencies of both components, producing negative deviations from Raoult's law.

While hydrogen bonding is frequently encountered in solutions, there are many other examples of weak chemical-bond formation between dissimilar molecules. The formation of such weak bonds is called complex formation—that is, formation of a new chemical species, called a complex, which is held together by weak forces that are chemical in nature rather than physical. Such complexes usually exist only in solution; because of their low stability, they cannot, in general, be isolated. The ability of molecules to form complexes has a strong effect on solution behaviour. For example, the solubility of a sparingly soluble species can be much increased by complex formation: the solubility of silver chloride in water is extremely small since silver chloride dissociates only slightly to silver ion and chloride ion; however, when a small quantity of ammonia is added, solubility rises dramatically because of the reaction of six molecules of ammonia with one silver ion to form the complex ion $Ag(NH_3)_6^+$. By tying up silver ions and forcing extensive dissociation of molecular silver chloride, the ammonia pulls silver chloride into aqueous solution.

In recent years there has been much interest in the use of computers to generate theoretical expressions for the activity coefficients of solutions. In many cases the calculations have been restricted to model systems, in particular to mixtures of hard-sphere (envisioned as billiard balls) molecules—*i.e.*, idealized molecules that have finite size but no forces of attraction. These calculations have produced a better understanding of the structure of simple liquid solutions since the manner in which nonpolar and non-hydrogen-bonding molecules arrange themselves in space is determined primarily by their size and shape and only secondarily by their attractive intermolecular forces. The results obtained for hard-sphere molecules can be extended to real molecules by applying corrections required for attractive forces and for the "softness" of the molecules—*i.e.*, the ability of molecules to interpenetrate (overlap) at high temperatures. While practical results are still severely limited and while the amount of required computer calculation is large even for simple binary systems, there is good reason to believe that advances in the theory of solution will increasingly depend on computerized, as opposed to analytical, models.

Solutions of electrolytes. Near the end of the 19th century, the properties of electrolyte solutions were investigated extensively by the early workers in physical chemistry. A suggestion of Svante August Arrhenius, a Swedish chemist, that salts of strong acids and bases (for example, sodium chloride) are completely dissociated into ions when in aqueous solution received strong support from electrical-conductivity measurements and from molecular-weight studies (freezing-point depression, boiling-point elevation, and osmotic pressure). These studies showed that the number of solute particles was larger than it would be if no dissociation occurred. For example, a 0.001 molal solution of a uni-univalent electrolyte (one in which each ion has a valence, or charge, of 1, and, when dissociated, two ions are produced) such as sodium chloride, Na^+Cl^-, exhibits colligative properties corresponding to a nonelectrolyte solution whose molality is 0.002; the colligative properties of a 0.001 molal solution of a univalent-divalent electrolyte (yielding three ions) such as magnesium bromide, $Mg^{2+}Br_2^-$, correspond to those of a nonelectrolyte solution with a molality of 0.003. At somewhat higher concentrations the experimental data showed some inconsistencies with Arrhenius' dissociation theory, and initially these were ascribed to incomplete, or partial, dissociation. In the years 1920–30, however, it was shown that these inconsistencies could be explained by electrostatic interactions (Coulomb forces) of the ions in solution. The current view of electrolyte solutions is that, in water at normal temperatures, the salts of strong acids and strong bases are completely dissociated into ions at all concentrations up to the solubility limit. At high concentrations Coulombic interactions may cause the formation of ion pairs, which implies that the ions are not dispersed uniformly in the solution but have a tendency to form two-ion aggregates in which a positive ion seeks the close proximity of a negative ion and vice versa. While the theory of dilute electrolyte solutions is well advanced, no adequate theory exists for concentrated electrolyte solutions primarily because of the long-range Coulomb forces that dominate in ionic solutions.

Arrhenius' theory of salts

Current theory of salts

The equilibrium properties of electrolyte solutions can be studied experimentally by electrochemical measurements, freezing-point depressions, solubility determinations, osmotic pressures, or measurements of vapour pressure. Most electrolytes, such as salts, are nonvolatile at ordinary temperature, and, in that event, the vapour pressure exerted by the solution is the same as the partial pressure of the solvent. The activity coefficient of the solvent can, therefore, be found from total-pressure measurements, and, using the Gibbs-Duhem equation, it is then possible to calculate the activity coefficient of the electrolyte solute. This activity coefficient is designated by $\gamma_\pm$ to indicate that it is a mean activity coefficient for the positive and negative ions. Since it is impossible to isolate positive ions and negative ions into separate containers, it is not possible to determine individual activity coefficients for the positive ions and for the negative ions. The mean activity coefficient $\gamma_\pm$ is so defined that it approaches a value of unity at very low molality where the ions are so far apart that they exert negligible influence on one another. For

small concentrations of electrolyte, the theory of Peter Debye, a Dutch-born American physical chemist, and Erich Hückel, a German chemist, relates $\gamma_\pm$ to the ionic strength, which is the sum of the products of the concentration of each ion (in moles per litre) and the square of its charge; the equation predicts that $\gamma_\pm$ decreases with rising ionic strength in agreement with experiment at very low ionic strength; at higher ionic strength, however, $\gamma_\pm$ rises, and in some cases $\gamma_\pm$ is greater than 1. The derivation of the Debye-Hückel theory clearly shows that it is limited to low concentrations. Many attempts have been made to extend the Debye-Hückel equation to higher electrolyte concentrations. One of the more successful attempts is based on the idea that the ions are solvated, which means that every ion is surrounded by a tight-fitting shell of solvent molecules.

The concept of solvation is often used to explain properties of aqueous solutions; one well-known property is the salting-out effect, in which the solubility of a nonelectrolyte in water is decreased when electrolyte is added. For example, the solubility of ethyl ether in water at 25° C is 0.91 mole percent, but, in an aqueous solution containing 15 weight percent sodium chloride, it is only 0.13 mole percent. This decrease in solubility can be explained by postulating that some of the water molecules cannot participate in the dissolution of the ether because they are tightly held (solvated) by sodium and chloride ions.

Electrolyte solutions have long been of interest in industry since many common inorganic chemicals are directly obtained, or else separated, by crystallization from aqueous solution. Further, many important chemical and metallurgical products (*e.g.*, aluminum) are obtained or refined by electrochemical processes that occur in liquid solution. In recent years there has been renewed interest in electrolyte solutions because of their relevance to fuel cells as a possible source of power for automobiles.

Electrolytes in physiology

The properties of electrolyte solutions also have large importance in physiology. Many molecules that occur in biological systems bear electric charges; a large molecule that has a positive electric charge at one end and a negative charge at the other is called a zwitterion. Very large molecules, such as those of proteins, may have numerous positive and negative charges; such molecules are called polyelectrolytes. In solution, the conformation (*i.e.*, the three-dimensional structure) of a large, charged molecule is strongly dependent on the ionic strength of the dissolving medium; for example, depending on the nature and concentration of salts present in the solvent, a polyelectrolyte molecule may coagulate into a ball, it may stretch out like a rod, or it may form a coil or helix. The conformation, in turn, is closely related to the molecule's physiological function. As a result, improved understanding of the properties of electrolyte solutions has direct consequences in molecular biology and medicine.

SOLUBILITIES OF SOLIDS AND GASES

Dissolution of a solid

Since the dissolution of one substance in another can occur only if there is a decrease in the Gibbs energy, it follows that, generally speaking, gases and solids do not dissolve in liquids as readily as do other liquids. To understand this, the dissolution of a solid can be visualized as occurring in two steps: in the first, the pure solid is melted at constant temperature to a pure liquid, and, in the second, that liquid is dissolved at constant temperature in the solvent. Similarly, the dissolution of a gas can be divided at some fixed pressure into two parts, the first corresponding to constant-temperature condensation of the pure gas to a liquid and the second to constant-temperature mixing of that liquid with solvent. In many cases, the pure liquids (obtained by melting or by condensation) may be hypothetical (*i.e.*, unstable and, therefore, physically unobtainable), but usually their properties can be estimated by reasonable extrapolations. It is found that the change in Gibbs energy corresponding to the first step is positive and, hence, in opposition to the change needed for dissolution. For example, at −10° C, ice is more stable than water, and, at 110° C and one atmosphere, steam is more stable than water. Therefore, the Gibbs energy of melting ice at −10° C is positive, and the Gibbs energy of condensing steam at one atmosphere and 110° C is also positive. For the second step, however, the change in Gibbs energy is negative; its magnitude depends on the equilibrium composition of the mixture. Owing to the positive Gibbs energy change that accompanies the first step, there is a barrier that makes it more difficult to dissolve solids and gases as compared with liquids.

For gases at normal pressures, the positive Gibbs energy of condensation increases with rising temperature, but, for solids, the positive Gibbs energy of melting decreases with rising temperature. For example, the change in energy, ΔG, of condensing steam at one atmosphere is larger at 120° C than it is at 110° C, while the change in energy of melting ice at −5° C is smaller than it is at −10° C. Thus, as temperature rises, the barrier becomes larger for gases but lower for solids, and therefore, with few exceptions, the solubility of a solid rises while the solubility of a gas falls as the temperature is raised.

For solids, the positive Gibbs energy "barrier" depends on the melting temperature. If the melting temperature is much higher than the temperature of the solution, the barrier is large, shrinking to zero when the melting temperature and solution temperature become identical.

Table 6: Solubilities of Some Gases* (mole percent)

	heptane	benzene	water
Hydrogen	0.069	0.026	0.0015
Nitrogen	0.12	0.45	0.0012
Methane	0.47	0.21	0.0024
Carbon dioxide	0.77	0.97	0.0608

*At one atmosphere partial pressure, 25° C.

Table 6 gives the solubilities of some common gases, and Table 7 the solubility of (solid) naphthalene in a few typical solvents. These solubilities illustrate the qualitative rule that "like dissolves like"; thus naphthalene, an aromatic hydrocarbon, dissolves more readily in another aromatic hydrocarbon such as benzene than it does in a chlorinated solvent such as carbon tetrachloride or in a hydrogen-bonded solvent such as methyl alcohol. By similar reasoning, the gas methane, a paraffinic hydrocarbon, dissolves more readily in another paraffin such as hexane than it does in water. In all three solvents, the gas hydrogen (which boils at −252.5° C) is less soluble than nitrogen (which boils at a higher temperature, −195.8° C).

Table 7: Solubility of Naphthalene in Various Solvents*

solvent	mole percent naphthalene
Benzene	24.1
Carbon tetrachloride	20.5
Hexane	9.0
Methyl alcohol	1.8
Water	0.0004

*At 20° C.

While exceptions may occur at very high pressures, the solubility of a gas in a liquid generally rises as the pressure of that gas increases. When the pressure of the gas is much larger than the vapour pressure of the solvent, the solubility is often proportional to the pressure. This proportionality is consistent with Henry's law, which states that, if the gas phase is ideal, the solubility x_2 of gas 2 in solvent 1 is equal to the partial pressure (the vapour-phase mole fraction y_2 times the total pressure P—*i.e.*, y_2P) divided by a temperature-dependent constant, $H_{2,1}$ (called Henry's constant), which is determined to a large extent by the intermolecular forces between solute 2 and solvent 1:

Henry's law

$$x_2 = \frac{y_2 P}{H_{2,1}}. \qquad (14)$$

When the vapour pressure of solvent 1 is small compared with the total pressure, the vapour-phase mole fraction of gas 2 is approximately one, and the solubility of the gas is proportional to the total pressure. (J.M.P./B.E.P.)

GASEOUS STATE

Structure

The remarkable feature of gases is that they appear to have no structure at all. They have neither a definite size nor shape, whereas ordinary solids have both a definite size and a definite shape, and liquids have a definite size, or volume, even though they adapt their shape to that of the container in which they are placed. Gases will completely fill any closed container; their properties depend on the volume of a container but not on its shape.

KINETIC-MOLECULAR PICTURE

Gases nevertheless do have a structure of sorts on a molecular scale. They consist of a vast number of molecules moving chaotically in all directions and colliding with one another and with the walls of their container. Beyond this, there is no structure—the molecules are distributed essentially randomly in space, traveling in arbitrary directions at speeds that are distributed randomly about an average determined by the gas temperature. The pressure exerted by a gas is the result of the innumerable impacts of the molecules on the container walls and appears steady to human senses because so many collisions occur each second on all sections of the walls. More subtle properties such as heat conductivity, viscosity (resistance to flow), and diffusion are attributed to the molecules themselves carrying the mechanical quantities of energy, momentum, and mass, respectively. These are called transport properties, and the rate of transport is dominated by the collisions between molecules, which force their trajectories into tortuous shapes. The molecular collisions are in turn controlled by the forces between the molecules and are described by the laws of mechanics.

Random nature of gases

Thus, gases are treated as a large collection of tiny particles subject to the laws of physics. Their properties are attributed primarily to the motion of the molecules and can be explained by the kinetic theory of gases. It is not obvious that this should be the case, and for many years a static picture of gases was instead espoused, in which the pressure, for instance, was attributed to repulsive forces between essentially stationary particles pushing on the container walls. How the kinetic-molecular picture finally came to be universally accepted is a fascinating piece of scientific history and is discussed briefly below in the section *Kinetic theory of gases*. Any theory of gas behaviour based on this kinetic model must also be a statistical one because of the enormous numbers of particles involved. The kinetic theory of gases is now a classical part of statistical physics and is indeed a sort of miniature display case for many of the fundamental concepts and methods of science. Such important modern concepts as distribution functions, cross sections, microscopic reversibility, and time-reversal invariance have their historical roots in kinetic theory, as does the entire atomistic view of matter.

NUMERICAL MAGNITUDES

When considering various physical phenomena, it is helpful for one to have some idea of the numerical magnitudes involved. In particular, there are several characteristics whose values should be known, at least within an order of magnitude (a factor of 10), in order for one to obtain a clear idea of the nature of gaseous molecules. These features include the size, average speed, and intermolecular separation at ordinary temperatures and pressures. In addition, other important considerations are how many collisions a typical molecule makes in one second under these conditions and how far such a typical molecule travels before colliding with another molecule. It has been established that molecules have sizes on the order of a few angstrom units (1 Å = 10^{-8} centimetre [cm]) and that there are about 6×10^{23} molecules in one mole, which is defined as the amount of a substance whose mass in grams is equal to its molecular weight (*e.g.*, 1 mole of water, H_2O, is 18.0152 grams). With this knowledge, one could calculate at least some of the gas values. It is interesting to see how the answers could be estimated from simple observations and then to compare the results to the accepted values that are based on more precise measurements and theories.

One of the easiest properties to work out is the average distance between molecules compared to their diameter; water will be used here for this purpose. Consider 1 gram of H_2O at 100° C and atmospheric pressure, which are the normal boiling point conditions. The liquid occupies a volume of 1.04 cubic centimetres (cm^3); once converted to steam it occupies a volume of 1.67×10^3 cm^3. Thus, the average volume occupied by one molecule in the gas is larger than the corresponding volume occupied in the liquid by a factor of $1.67 \times 10^3/1.04$, or about 1,600. Since volume varies as the cube of distance, the ratio of the mean separation distance in the gas to that in the liquid is roughly equal to the cube root of 1,600, or about 12. If the molecules in the liquid are considered to be touching each other, the ratio of the intermolecular separation to the molecular diameter in ordinary gases is on the order of 10 under ordinary conditions. It should be noted that the actual separation and diameter cannot be determined in this way; only their ratio can be calculated.

It is also relatively simple to estimate the average speed of gas molecules. Consider a sound wave in a gas, which is just the propagation of a small pressure disturbance. If pressure is attributed to molecular impacts on a test surface, then surely a pressure disturbance cannot travel faster than the molecules themselves. In other words, the average molecular speed in a gas should be somewhat greater than the speed of sound in the gas. The speed of sound in air at ordinary temperatures is about 330 metres per second (m/s), so the molecular speed will be estimated here to be somewhat greater, say, about 5×10^4 centimetres per second (cm/s). This value depends on the particular gas and the temperature, but it will be sufficient for the kind of estimates sought here.

Average molecular speed

The average molecular speed, along with an observed rate of the diffusion of gases, can be used to estimate the length and tortuosity of the path traveled by a typical molecule. If a bottle of ammonia is opened in a closed room, at least a few minutes pass before the ammonia can be detected at a distance of just one metre. (Ammonia, NH_3, is a gas; the familiar bottle of "ammonia" typically seen is actually a solution of the gas in water.) Yet, if the ammonia molecules traveled directly to an observer at a speed somewhat faster than that of sound, the odour should be detectable in only a few milliseconds. The explanation for the discrepancy is that the ammonia molecules collide with many air molecules, and their paths are greatly distorted as a result. For a quantitative estimate of the diffusion time, a more controlled system must be considered, because even gentle stray air currents in a closed room greatly speed up the spreading of the ammonia. To eliminate the effect of such air currents, a closed tube—say, a glass tube one centimetre in diameter and one metre in length—can be used. A small amount of ammonia gas is released at one end, and both ends are then closed. In order to measure how long it takes for the ammonia to travel to the other end, a piece of moist red litmus paper might be used as a detector; it will turn blue when the ammonia reaches it. This process takes quite a long time—about several hours—because diffusion occurs at such a slow rate. In this case, the time will be taken to be approximately 3 hours, or roughly 10^4 seconds (s). During this time interval, a typical ammonia molecule actually travels a distance of $(5 \times 10^4 \text{ cm/s})(10^4 \text{ s}) = 5 \times 10^8$ cm = 5,000 kilometres (km), roughly the distance across the United States. In other words, such a molecule travels a total distance of five million metres in order to progress a net distance of only one metre.

The solution to a basic statistical problem can be used to estimate the number of collisions such a typical diffusing molecule experienced (N) and the average distance traveled between collisions (l), called the mean free path.

The product of N and l must equal the total distance traveled—*i.e.*, $Nl = 5 \times 10^8$ cm. This distance can be thought of as a chain 5,000 km long, made up of N links, each of length l. The statistical question then is as follows: If such a chain is randomly jumbled, how far apart will its ends be on the average? This end-to-end distance corresponds to the length of the diffusion tube (one metre). This is a venerable statistical problem that recurs in many applications. One of the more vivid ways of illustrating the concept is known as the "drunkard's walk." In this scenario a drunkard takes steps of length l but, because of inebriation, takes them in random directions. After N steps, how far will he be from his starting point? The answer is that his progress is proportional not to N but to $N^{1/2}$. For example, if the drunkard takes four steps, each of length l, he will end up at a distance of $2l$ from his starting point. Gas molecules move in three dimensions, whereas the drunkard moves in two dimensions; however, the result is the same. Thus, the square root of N multiplied by the length of the mean free path equals the length of the diffusion tube: $N^{1/2}l = 10^2$ cm. From the equations for Nl and $N^{1/2}l$, it can readily be calculated that $N = 2.5 \times 10^{13}$ collisions and $l = 2.0 \times 10^{-5}$ cm. The mean time between collisions, τ, is found by dividing the time of the diffusion experiment by the number of collisions during that time: $\tau = (10^4)/(2.5 \times 10^{13}) = 4 \times 10^{-10}$ seconds between collisions, corresponding to a collision frequency of 2.5×10^9 collisions per second. It is thus understandable that gases appear to be continuous fluids on ordinary scales of time and distance.

Random walk

Molecular sizes can be estimated from the foregoing information on the intermolecular separation, speed, mean free path, and collision rate of gas molecules. It would seem logical that large molecules should have a better chance of colliding than do small molecules. The collision frequency and mean free path must therefore be related to molecular size. To find this relationship, consider a single molecule in motion; during a time interval t it will sweep out a certain volume, hitting any other molecules present in this so-called collision volume. If molecules are located by their centres and each molecule has a diameter d, then the collision volume will be a long cylinder of cross-sectional area πd^2. The cylinder must be sufficiently long to include enough molecules so that good statistics on the number of collisions are obtained, but otherwise the length does not matter. If the molecule is observed for a time t, then the length of the collision cylinder will be $\bar{v}t$, where $\bar{v}$ is the average speed of the molecule, and the volume of the cylinder will be $(\pi d^2)(\bar{v}t)$, the product of its cross-sectional area and its length. Every molecule in the cylinder will be struck within time t, so the number of molecules in the collision cylinder will equal the number of collisions that occur in time t. Each collision will put a kink in the cylinder, but this will not affect the results as long as the number of collisions is not too large. If the gas is uniform, the number of molecules per volume will be consistent throughout the entire gas. Suppose that there are N molecules in volume V; then there will be $(N/V)(\pi d^2)(\bar{v}t)$ molecules in the collision volume; this is the number of collisions in time t. The mean free path is equal to the total length of the collision cylinder divided by the number of collisions that occur in it:

$$l = \frac{(\bar{v}t)}{(N/V)(\pi d^2)(\bar{v}t)} = \frac{1}{(N/V)(\pi d^2)}.$$

Since l has been shown to be roughly 2.0×10^{-5} cm, d could be calculated if N/V was known.

It is relatively easy to find $(N/V)d^3$, from which both d and N/V can be determined. Recall that the volume of one gram of steam is about 1,600 times larger than the volume of one gram of liquid water. In other words, there are roughly 1,600 N molecules in a volume V of liquid, and, if the molecules are just touching (*i.e.*, the separation distance between their centres is one molecular diameter), the volume V of the liquid is 1,600 Nd^3. When this equation for volume is combined with the above expression for l, the following values are obtained: $d = \pi(2.0 \times 10^{-5})/1{,}600 = 3.9 \times 10^{-8}$ cm $= 3.9$ Å, and $N/V = 1/\pi d^2 l = 1.0 \times 10^{19}$ molecules per cubic centimetre. Thus, a typical molecule is exceedingly small, and there is an impressively large number of them in one cubic centimetre of gas.

Between collisions, a gas molecule travels a distance of about $l/d = (2.0 \times 10^{-5})/(3.9 \times 10^{-8}) = 500$ times its diameter. Since it was calculated above that the average separation between molecules is about 10 times the molecular diameter, the mean free path is approximately 50 times greater than the mean molecular separation. Accordingly, a typical molecule passes roughly 50 other molecules before it hits one.

The following is a summary of the above estimates of molecular quantities in a gas, with a little spread in the numbers to allow for molecules both smaller and larger than the typical ones used here—which are H_2O, NH_3, and the nitrogen (N_2) plus oxygen (O_2) mixture that is air—and to allow for the fact that some of these quantities depend on temperature and pressure. It is important to note that these estimates and calculations are rather simplified, although fundamentally correct, and that there may well be missing factors such as $3\pi/8$ or $\sqrt{2}$. The numerical estimates for gases at ordinary pressure and temperature are:

molecular diameter	10^{-8} to 10^{-7} cm
molecular number density	10^{19} molecules/cm^3
average molecular speed	10^4 to 10^5 cm/s
average distance between molecules	10^{-7} to 10^{-6} cm
collision rate per molecule	10^9 to 10^{10} collisions/s
average time between collisions	10^{-10} to 10^{-9} s
average distance traveled between collisions (mean free path)	10^{-5} to 10^{-4} cm

The general impression of gas molecules given by these numbers is that they are exceedingly small, that there are enormous numbers of them in even one cubic centimetre, that they are moving very fast, and that they collide many times in one second. Two other facts are especially important. The first is that the lengths involved, especially the mean free path, are minute compared with ordinary lengths, even with the diameter of a capillary tube. This means that gas behaviour and properties are dominated by collisions between molecules and that collisions with walls play only a secondary (though important) role. The second is that the mean free path is much larger than the molecular diameter. Thus, collisions between pairs of molecules are of paramount importance in determining ordinary gas behaviour, while collisions that involve three or more molecules at the same time can basically be ignored.

A cautious reader might feel a bit uneasy about the glibness of the preceding estimates, so a simple check will be made here by calculating the number of molecules in one mole of gas, a quantity known as Avogadro's number. The number density of a gas was approximated to be about 1.0×10^{19} molecules per cubic centimetre, and from experiment it is known that 1 mole of gas occupies a volume of about 25 litres (2.5×10^4 cubic centimetres) under ordinary conditions. Using these values, an estimate of Avogadro's number is $(1.0 \times 10^{19})(2.5 \times 10^4) = 2.5 \times 10^{23}$ molecules per mole. This deviates somewhat from the accepted value of 6.022×10^{23} molecules per mole, but the order of magnitude is certainly correct. In point of historical fact, a value for Avogadro's number as good as this estimate was not obtained until 1865, when Josef Loschmidt in Vienna made a calculation similar to the one here but based on gas viscosity rather than on gas diffusion. In the older German scientific literature, Avogadro's number is often referred to as Loschmidt's number for this reason. In current English-language scientific literature, Loschmidt's number is usually taken to mean the number of gas molecules in one cubic centimetre at 0° C and one atmosphere pressure (2.687×10^{19} molecules per cubic centimetre).

Loschmidt's number

There are other ways by which molecular sizes and Avogadro's number could have been estimated, such as from the spreading of a surface oil film on water or from the surface tension and the energy of evaporation of a liquid, but they will not be discussed here.

The foregoing picture of a gas as a collection of molecules

dominated by binary molecular collisions is in reality only a limited view. Two limitations of the model are briefly discussed below.

FREE-MOLECULE GAS

The mean free path in a gas may easily be increased by decreasing the pressure. If the pressure is halved, the mean free path doubles in length. Thus, at low enough pressures the mean free path can become sufficiently large that collisions of the gas molecules with surfaces become more important than collisions with other gas molecules. In such a case, the molecules can be envisioned as moving freely through space until they encounter some solid surface; hence, they are termed free-molecule gases. Such gases are sometimes called Knudsen gases, after the Danish physicist Martin Knudsen, who studied them experimentally. Many of their properties are strikingly different from those of ordinary gases (also known as continuum gases). A radiometer is a four-vaned mill that depends essentially on free-molecule effects. A temperature difference in the free-molecule gas causes a thermomolecular pressure difference that drives the vanes. The radiometer will stop spinning if enough air leaks into its glass envelope. (It will also stop spinning if all the air is removed from the envelope.) The flight of objects at high altitudes, where the mean free path is very long, is also subject to free-molecule effects. Such effects can even occur at ordinary pressures if a significant physical dimension becomes small enough. Important examples are found in many chemical process industries, where reactions are forced by catalysts to proceed at reasonable speeds. Many of these catalysts are porous materials whose pore sizes are smaller than molecular mean free paths. The speed of the desired chemical reaction may be controlled by how fast the reactant gases diffuse into the porous catalyst and by how fast the product gases can diffuse out so more reactants can enter the pores.

There is a large transition region between free-molecule behaviour and continuum behaviour, where both molecule-molecule and molecule-surface collisions are significant. This region is rather difficult to describe theoretically and remains an active field of research.

CONTINUITY OF GASEOUS AND LIQUID STATES

It may be somewhat surprising to learn that there is no fundamental distinction between a gas and a liquid. It was noted above that a gas occupies a volume about 1,600 times greater than that of an equal weight of liquid. The question arises as to the behaviour of a gas that has been compressed to 1/1,600 of its volume by application of sufficiently high pressure. If this compression is carried out above a specific temperature called the critical temperature, which is different for each gas, no phase change occurs, and the resulting substance is a gas that is just as dense as a liquid. If the compression is carried out at a fixed temperature below the critical temperature, an astonishing phenomenon occurs—at a particular pressure liquid suddenly forms. Attempts to compress the gas further simply increase the amount of liquid present and decrease the amount of gas, with the pressure remaining constant until all the gas has been converted to liquid. The applied pressure must subsequently rise a great deal to reduce the volume further, since liquids are much less compressible than gases.

Condensation

The abrupt condensation of a gas to a liquid usually does not seem astonishing because it is so commonplace—nearly everyone has boiled water, for example, which is the reverse process. From the standpoint of the kinetic-molecular theory of gases, however, it is something of a mystery. Why does it occur so abruptly and only at temperatures below a critical temperature? Equations have been written down that describe condensation, but an explanation is still lacking in the sense that no one has been able to show that it must occur, given only the forces between the molecules and the fact that their motion is described by ordinary mechanics. Condensation, which is an example of a first-order phase transition, remains one of the outstanding unsolved problems of statistical physics.

The critical temperature marks the separation between an abrupt change and a continuous change. Other peculiar phenomena occur near the critical temperature. The densities of the coexisting liquid and gas (which is usually called a vapour in this case) become closer as the critical temperature is approached from below, and at the critical temperature they are identical. There is a unique point for every fluid, called the critical point. It is described by a critical temperature, a critical volume, and a critical pressure, at which liquid and vapour become identical. Above that temperature there is no distinction between gas and liquid; there is only a single fluid. Moreover, it is possible to pass continuously from an apparently definite gas or vapour to an apparently definite liquid with no abrupt condensation occurring. This can be accomplished by heating the vapour above the critical temperature while keeping the volume constant, then compressing it to a high density characteristic of a liquid, and finally cooling it at constant volume to its original temperature, where it is now clearly a liquid.

In short, gases and liquids are just the extreme stages of a fluid, with no fundamental distinction between the two. For this reason, an arbitrary decision has been made for the present discussion to define what is meant by the gaseous state. The definition will be based on the number density (*i.e.*, molecules per unit volume): the number density of the fluid must be low enough that only collisions between two molecules at a time need to be considered. More specifically, the mean free path must be much larger than the molecular diameter. Such a fluid shall be termed a dilute gas.

A few brief historical remarks are in order before leaving the subject of the continuity of the gaseous and liquid states. The first extensive experimental study that clearly demonstrated the phenomena involved was performed on carbon dioxide, CO_2. (Carbon dioxide, whose solid form is called dry ice, has a critical temperature of 31° C.) The experiment was conducted by Thomas Andrews at what is now the Queen's University of Belfast in Northern Ireland, and its results were summarized in 1869 in a Bakerian lecture to the Royal Society of London entitled "On the Continuity of the Gaseous and Liquid States of Matter." In 1873 a Dutch thesis was presented to the University of Leiden by Johannes D. van der Waals with virtually the same title (but in Dutch) as Andrews' lecture. In his study van der Waals used some ingenious approximations to obtain a simple equation relating the pressure, temperature, and molar volume of a fluid, based on a model that considered molecules as hard spheres with weak long-range attractive forces between them. This equation can be used to locate the critical point of a system, and it is also consistent with the occurrence of condensation when supplemented with a thermodynamic condition. This is possibly one of the most-quoted but little-read theses in science. Nevertheless, van der Waals started a scientific trend that continues to the present. His pressure-volume-temperature relation, called an equation of state, is the standard equation of state for real gases in physical chemistry, and at least one new equation of state is proposed every year in an attempt to improve on its quantitative accuracy (which is not very good). It furnished the impetus for the development of theories of liquids and of solutions. The equation is compatible with a unifying idea called the principle of corresponding states. This principle states that, if the pressure (p), volume (V), and temperature (T) of a gas are replaced, respectively, with the corresponding reduced variables—*i.e.*, the pressure divided by the critical pressure (p/p_c), the volume divided by the critical volume (V/V_c), and the temperature divided by the critical temperature (T/T_c)—all gases will behave in essentially the same manner.

The van der Waals equation

The critical point has itself proved to be a rich and deep subject. The gas-liquid critical point turns out to be only one of many types of critical points, including those of a magnetic variety, with the common feature that long-range correlations develop regardless of the molecular details of the system. That is, any small part of a system near its critical point seems to "know" what quite distant parts are doing. The mathematical description of the behaviour of a system near its critical point also becomes rather unusual.

Behaviour and properties

Statistical methods

The enormous number of molecules in even a small volume of a dilute gas produces not complication, as might be expected, but rather simplification. The reason is that ordinarily only statistical averages are observed in the study of the behaviour and properties of gases, and statistical methods are quite accurate when large numbers are involved. Compared to the numbers of molecules involved, there are only a few properties of gases that warrant attention here, namely, pressure, density, temperature, internal energy, viscosity, heat conductivity, and diffusivity. (More subtle properties can be brought into view by the application of electric and magnetic fields, but they are of minor interest.)

It is a remarkable fact that these properties are not independent. If two are known, the rest can be determined from them. That is to say, for a given gas, the specification of only two properties—usually chosen to be temperature and density or temperature and pressure—fixes all the others. Thus, if the temperature and density of carbon dioxide are specified, the gas can have only one possible pressure, one internal energy, one viscosity, and so on. In order to determine the values of these other properties, they must either be measured or calculated from the known properties of the molecules themselves. Such calculations are the ultimate goal of statistical mechanics and kinetic theory, and dilute gases constitute the case for which the most progress toward that goal has been made.

In discussing the behaviour of gases, it is useful to separate the equilibrium properties and the nonequilibrium transport properties. By definition, a system in equilibrium can undergo no net change unless some external action is performed on it (*e.g.*, pushing in a piston or adding heat). Its behaviour is steady with time, and no changes appear to be occurring, even though the molecules are in ceaseless motion. In contrast, the nonequilibrium properties describe how a system responds to some external action, such as the imposition of a temperature or pressure difference. Equilibrium behaviour is much easier to analyze, because any change that occurs on the molecular level must be compensated by some other change or changes on the molecular level in order for the system to remain in equilibrium.

EQUILIBRIUM PROPERTIES

Among the most obvious properties of a dilute gas, other than its low density compared with liquids and solids, are its great elasticity or compressibility and its large volume expansion on heating. These properties are nearly the same for all dilute gases, and virtually all such gases can be described quite accurately by the following universal equation of state:

$$pv = RT. \tag{15}$$

Ideal gas equation of state

This expression is called the ideal, or perfect, gas equation of state, since all real gases show small deviations from it, although these deviations become less significant as the density is decreased. Here p is the pressure, v is the volume per mole, or molar volume, R is the universal gas constant, and T is the absolute thermodynamic temperature. To a rough degree, the expression is accurate within a few percent if the volume is more than 10 times the critical volume; the accuracy improves as the volume increases. The expression eventually fails at both high and low temperatures, owing to ionization at high temperatures and to condensation to a liquid or solid at low temperatures.

The ideal gas equation of state is an amalgamation of three ideal gas laws that were formulated independently. The first is Boyle's law, which refers to the elastic properties of the gas; it was described by the Anglo-Irish scientist Robert Boyle in 1662 in his famous "... Experiments ... Touching the Spring of the Air ...." It states that the volume of a gas at constant temperature is inversely proportional to the pressure; *i.e.*, if the pressure on a gas is doubled, for example, its volume decreases by one-half. The second, usually called Charles's law, is concerned with the thermal expansion of the gas. It is named in honour of the French experimental physicist Jacques-Alexandre-César Charles for the work he carried out in about 1787. The law states that the volume of a gas at constant pressure is directly proportional to the absolute temperature; *i.e.*, an increase of temperature of 1° C at room temperature causes the volume to increase by about 1 part in 300, or 0.3 percent. The third law embodied in equation (15) is based on the 1811 hypothesis of the Italian scientist Amedeo Avogadro—namely, that equal volumes of gases at the same temperature and pressure contain equal numbers of particles. The number of particles (or molecules) is proportional to the number of moles n, the constant of proportionality being Avogadro's number, N_0. Thus, at constant temperature and pressure the volume of a gas is proportional to the number of moles. If the total volume V contains n moles of gas, then only $v = V/n$ appears in the equation of state. By measuring the quantity of gas in moles rather than grams, the constant R is made universal; if mass were measured in grams (and hence v in volume per gram), then R would have a different value for each gas.

The ideal gas law is easily extended to mixtures by letting n represent the total number of moles of all species present in volume V. That is, if there are n_1 moles of species 1, n_2 moles of species 2, etc., in the mixture, then $n = n_1 + n_2 + \cdots$ and $v = V/n$ as before. This result can also be rewritten and reinterpreted in terms of the partial pressures of the different species, such that $p_1 = n_1 RT/V$ is the partial pressure of species 1 and so on. The total pressure is then given as $p = p_1 + p_2 + \cdots$. This rule is known as Dalton's law of partial pressures in honour of the British chemist and physicist John Dalton, who formulated it about 1801.

A brief aside on units and temperature scales is in order. The (metric) unit of pressure in the scientific international system of units (known as the SI system) is newton per square metre (N/m^2), where one newton (N) is the force that gives a mass of one kilogram an acceleration of 1 m/s^2. The unit N/m^2 is given the name pascal (Pa), where one standard atmosphere is exactly 101,325 Pa (approximately 14.7 pounds per square inch). The unit of volume in the SI system is the cubic metre ($1\ m^3 = 10^6\ cm^3$), and the unit of temperature is the kelvin (K). The Kelvin thermodynamic temperature scale is defined through the laws of thermodynamics so as to be absolute or universal, in the sense that its definition does not depend on the specific properties of any particular kind of matter. Its numerical values, however, are assigned by defining the triple point of water—*i.e.*, the unique temperature at which ice, liquid water, and water vapour are all in equilibrium—to be exactly 273.16 K. The freezing point of water under one atmosphere of air then turns out to be (by measurement) 273.1500 K. The freezing point is 0° on the Celsius scale (or 32° on the Fahrenheit scale), by definition. The precise thermodynamic definition of the Kelvin scale and the rather peculiar number chosen to define its numerical values (*i.e.*, 273.16) are historical choices made so that the ideal gas equation of state will have the simple mathematical form given by the right-hand side of equation (15).

Kelvin scale

The gas constant R is determined by measurement. The best value so far obtained is that of the U.S. National Institute of Standards and Technology—namely, 8.314471 J/mol · K. Here the unit J is one of work or energy, one joule (J) being equal to one newton-metre.

Once the equation of state is known for an ideal gas, only its internal energy, E, needs to be determined in order for all other equilibrium properties to be deducible from the laws of thermodynamics. That is to say, if the equation of state and the internal energy of a fluid are known, then all the other thermodynamic properties (*e.g.*, enthalpy, entropy, and free energy) are fixed by the condition that it must be impossible to construct perpetual motion machines from the fluid. Proofs of such statements are usually rather subtle and involved and constitute a large part of the subject of thermodynamics, but conclusions based on thermodynamic principles are among the most reliable results of science.

A thermodynamic result of relevance here is that the ideal gas equation of state requires that the internal energy depend on temperature alone, not on pressure or density.

The actual relationship between E and T must be measured or calculated from known molecular properties by means of statistical mechanics. The internal energy is not directly measurable, but its behaviour can be determined from measurements of the molar heat capacity (*i.e.*, the specific heat) of the gas. The molar heat capacity is the amount of energy required to raise the temperature of one mole of a substance by one degree; its units in the SI system are J/mol · K. A system with many kinds of motion on a molecular scale absorbs more energy than one with only a few kinds of motion. The interpretation of the temperature dependence of E is particularly simple for dilute gases, as is shown in the discussion of the kinetic theory of gases below. The following highlights only the major aspects.

Contributions to internal energy

Every gas molecule moves in three-dimensional space, and this translational motion contributes $(3/2)RT$ (per mole) to the internal energy E. For monatomic gases, such as helium, neon, argon, krypton, and xenon, this is the sole energy contribution. Gases that contain two or more atoms per molecule also contribute additional terms because of their internal motions:

$$E \text{ (per mole)} = \frac{3}{2}RT + E_{int}, \qquad (16)$$

where E_{int} may include contributions from molecular rotations and internal vibrations and occasionally from internal electronic excitations. Some of these internal motions may not contribute at ordinary temperatures because of special conditions imposed by quantum mechanics, however, so that the temperature dependence of E_{int} can be rather complex.

The extension to gas mixtures is straightforward—the total internal energy E (per mole) is the weighted sum of the internal energies of each of the species: $nE = n_1E_1 + n_2E_2 + \cdots$, where $n = n_1 + n_2 + \cdots$.

It is the task of the kinetic theory of gases to account for these results concerning the equation of state and the internal energy of dilute gases.

TRANSPORT PROPERTIES

The following is a summary of the three main transport properties: viscosity, heat conductivity, and diffusivity. These properties correspond to the transfer of momentum, energy, and matter, respectively.

Viscosity. All ordinary fluids exhibit viscosity, which is a type of internal friction. A continuous application of force is needed to keep a fluid flowing, just as a continuous force is needed to keep a solid body moving in the presence of friction. Consider the case of a fluid slowly flowing through a long capillary tube. A pressure difference of Δp must be maintained across the ends to keep the fluid flowing, and the resulting flow rate is proportional to Δp. The rate is inversely proportional to the viscosity (η) since the friction that opposes the flow increases as η increases. It also depends on the geometry of the tube, but this effect will not be considered here. The SI units of η are $N \cdot s/m^2$ or $Pa \cdot s$. An older unit of the centimetre-gram-second version of the metric system that is still often used is the poise (1 $Pa \cdot s = 10$ poise). At 20° C the viscosity of water is 1.0×10^{-3} $Pa \cdot s$ and that of air is 1.8×10^{-5} $Pa \cdot s$. To a rough approximation, liquids are about 100 times more viscous than gases.

There are three important properties of the viscosity of dilute gases that seem to defy common sense. All can be explained, however, by the kinetic theory (see below *Kinetic theory of gases*). The first property is the lack of a dependence on pressure or density. Intuition suggests that gas viscosity should increase with increasing density, inasmuch as liquids are much more viscous than gases, but gas viscosity is actually independent of density. This result can be illustrated by a pendulum swinging on a solid support. It eventually slows down owing to the viscous friction of the air. If a bell jar is placed over the pendulum and half the air is pumped out, the air remaining in the jar damps the pendulum just as fast as a full jar of air would have done. Robert Boyle noted this peculiar phenomenon in 1660, but his results were largely either ignored or forgotten. The Scottish chemist Thomas Graham studied the flow of gases through long capillaries, which he called transpiration, in 1846 and 1849, but it was not until 1877 that the German physicist O.E. Meyer pointed out that Graham's measurements had shown the independence of viscosity on density. Prior to Meyer's investigations, the kinetic theory had suggested the result, so he was looking for experimental proof to support the prediction. When James Clerk Maxwell discovered (in 1865) that his kinetic theory suggested this result, he found it difficult to believe and attempted to check it experimentally. He designed an oscillating disk apparatus (which is still much copied) to verify the prediction.

The second unusual property of viscosity is its relationship with temperature. One might expect the viscosity of a fluid to increase as the temperature is lowered, as suggested by the phrase "as slow as molasses in January." The viscosity of a dilute gas behaves in exactly the opposite way: the viscosity increases as the temperature is raised. The rate of increase varies approximately as T^s, where s is between ½ and 1, and depends on the particular gas. This behaviour was clearly established in 1849 by Graham.

Temperature-viscosity relationship

The third property pertains to the viscosity of mixtures. A viscous syrup, for example, can be made less so by the addition of a liquid with a lower viscosity, such as water. By analogy, one would expect that a mixture of carbon dioxide, which is fairly viscous, with a gas like hydrogen, which is much less viscous, would have a viscosity intermediate to that of carbon dioxide and hydrogen. Surprisingly, the viscosity of the mixture is even greater than that of carbon dioxide. This phenomenon was also observed by Graham in 1849.

Finally, there is no obvious correlation of gas viscosity with molecular weight. Heavy gases are often more viscous than light gases, but there are many exceptions, and no simple pattern is apparent.

Heat conduction. If a temperature difference is maintained across a fluid, a flow of energy through the fluid will result. The energy flow is proportional to the temperature difference according to Fourier's law, where the constant of proportionality (aside from the geometric factors of the apparatus) is called the heat conductivity or thermal conductivity of the fluid, λ. Mechanisms other than conduction can transport energy, in particular convection and radiation; here it is assumed that these can be eliminated or adjusted for. The SI units for λ are $J/m \cdot s \cdot K$ or watt per metre degree ($W/m \cdot K$), but sometimes calories are used for the energy term instead of joules (one calorie = 4.184 J). At 20° C the thermal conductivity of water is 0.60 $W/m \cdot K$, and that of many organic liquids is roughly only one-third as large. The thermal conductivity of air at 20° C is only about 2.5×10^{-2} $W/m \cdot K$. To a rough approximation, liquids conduct heat about 10 times better than do gases.

The properties of the thermal conductivity of dilute gases parallel those of viscosity in some respects. The most striking is the lack of dependence on pressure or density. Based on this fact, there seems to be no advantage to pumping out the inner chambers of thermos bottles. As far as conduction is concerned, it does not provide any benefits until practically all the air has been removed and free-molecule conduction is occurring. Convection, however, does depend on density, so some degree of insulation is provided by pumping out only some of the air.

The thermal conductivity of a dilute gas increases with increasing temperature, much like its viscosity. In this case, such behaviour does not seem particularly odd, probably because most people do not have a preconceived idea of how thermal conductivity should behave, unlike the situation with viscosity.

There are some differences in the behaviour of thermal conductivity and viscosity; one of the most notable has to do with mixtures. At first glance the thermal conductivity of a gaseous mixture seems to be as expected, since it falls between the conductivities of its components, but a closer look reveals an odd regularity. The conductivity of the mixture is always less than an average based on the number of moles (or molecules) of each component in the mixture. This appears to be related to the different effect that molecular weight has on thermal conductivity and

Conductivity of mixtures

viscosity. Light gases are usually better conductors than are heavy gases, whereas heavy gases are often (but not always) more viscous than are light gases. There also seems to be some correlation between molar heat capacity and thermal conductivity. The foregoing properties of thermal conductivity pose more puzzles that the kinetic theory of gases must address.

Diffusion. Diffusion in dilute gases is in some ways more complex, or at least more subtle, than either viscosity or thermal conductivity. First, a mixture is necessarily involved, inasmuch as a gas diffusing through itself makes no sense physically unless the molecules are in some way distinguishable from one another. Second, diffusion measurements are rather sensitive to the details of the experimental conditions. This sensitivity can be illustrated by the following considerations.

Light molecules have higher average speeds than do heavy molecules at the same temperature. This result follows from kinetic theory, as explained below, but it can also be seen by noting that the speed of sound is greater in a light gas than in a heavy gas. This is the basis of the well-known demonstration that breathing helium causes one to speak with a high-pitched voice. If a light and a heavy gas are interdiffusing, the light molecules should move into the heavy-gas region faster than the heavy molecules move into the light-gas region, thereby causing the pressure to rise in the heavy-gas region. If the diffusion takes place in a closed vessel, the pressure difference drives the heavy gas into the light-gas region at a faster rate than it would otherwise diffuse, and a steady state is quickly reached in which the number of heavy molecules traveling in one direction equals, on the average, the number of light molecules traveling in the opposite direction. This method, called equimolar countercurrent diffusion, is the usual manner in which gaseous diffusion measurements are now carried out.

The steady-state pressure difference that develops is almost unmeasurably small unless the diffusion occurs through a fine capillary or a fine-grained porous material. Nevertheless, experimenters have been able to devise clever schemes either to measure it or to prevent its development. The first to do the latter was Graham in 1831; he kept the pressure uniform by allowing the gas mixture to flow. The results of this work now appear in elementary textbooks as Graham's law of diffusion. Most of these accounts are incorrect or incomplete or both, owing to the fact that the writers confuse the uniform-pressure experiment either with the equal countercurrent experiment or with the phenomenon of effusion (described below in the section *Kinetic theory of gases*). Graham also performed equal countercurrent experiments in 1863, using a long closed-tube apparatus he devised. This sort of apparatus is now usually called a Loschmidt diffusion tube after Loschmidt, who used a modified version of the tube in 1870 to make a series of accurate diffusion measurements on a number of gas pairs.

A quantitative description of diffusion follows. A composition difference in a two-component gas mixture causes a relative flow of the components that tends to make the composition uniform. The flow of one component is proportional to its concentration difference, and in an equal countercurrent experiment this is balanced by an equal and opposite flow of the other component. The constant of proportionality is the same for both components and is called the diffusion coefficient, D_{12}, for that gas pair. This relationship between the flow rate and the concentration difference is called Fick's law of diffusion. The SI units for the diffusion coefficient are square metres per second (m^2/s). Diffusion, even in gases, is an extremely slow process, as was pointed out above in estimating molecular sizes and collision rates. Gaseous diffusion coefficients at one atmosphere pressure and ordinary temperatures lie largely in the range of 10^{-5} to 10^{-4} m^2/s, but diffusion coefficients for liquids and solutions lie in the range of only 10^{-10} to 10^{-9} m^2/s. To a rough approximation, gases diffuse about 100,000 times faster than do liquids.

Fick's law of diffusion

Diffusion coefficients are inversely proportional to total pressure or total molar density and are therefore reported by convention at a standard pressure of one atmosphere. Doubling the pressure of a diffusing mixture halves the diffusion coefficient, but the actual rate of diffusion remains unchanged. This seemingly paradoxical result occurs because doubling the pressure also doubles the concentration, according to the ideal gas equation of state, and hence doubles the concentration difference, which is the driving force for diffusion. The two effects exactly compensate.

Diffusion coefficients increase with increasing temperature at a rate that depends on whether the pressure or the total molar density is held constant as the temperature is changed. If the rate increases as T^s at constant molar density (where s usually lies between $\frac{1}{2}$ and 1), then it will increase as T^{1+s} at constant pressure, according to the ideal gas equation of state.

Perhaps the most surprising property of gaseous diffusion coefficients is that they are virtually independent of the mixture's composition, varying by at most a few percent over the whole composition range, even for very dissimilar gases. A trace of hydrogen, for example, diffuses through carbon dioxide at virtually the same rate that a trace of carbon dioxide diffuses through hydrogen. Liquid mixtures do not behave this way, and liquid diffusion coefficients may vary by as much as a factor of 10 from one end of the composition range to the other. The lack of composition dependence of gaseous diffusion coefficients is one of the odder properties to be explained by kinetic theory.

Thermal diffusion. If a temperature difference is applied to a uniform mixture of two gases, the mixture will partially separate into its components, with the heavier, larger molecules usually (but not invariably) concentrating at the lower temperature. This behaviour was predicted theoretically before it was observed experimentally, but a rather elaborate explanation was required because simple theory suggests no such phenomenon. It was predicted in 1911–12 by David Enskog in Sweden and independently in 1917 by Sydney Chapman in England, but the validity of their theoretical results was questioned until Chapman (who was an applied mathematician) enlisted the aid of the chemist F.W. Dootson to verify it experimentally.

Thermal diffusion can be used to separate isotopes. The amount of separation for any reasonable temperature difference is quite small for isotopes, but the effect can be amplified by combining it with slow thermal convection in a columnar arrangement devised in 1938 by Klaus Clusius and Gerhard Dickel in Germany. While the apparatus is quite simple, the theory of its operation is not: a long cylinder with a diameter of several centimetres is mounted vertically with an electrically heated hot wire along its central axis. The thermal diffusion occurs horizontally between the hot wire and the cold wall of the cylinder, and the convection takes place vertically to bring new gas regions into contact.

The diffusion thermoeffect

There is also an effect that is the inverse of thermal diffusion, called the diffusion thermoeffect, in which an imposed concentration difference causes a temperature difference to develop. That is, a diffusing gas mixture develops small temperature differences, on the order of 1° C, which die out as the composition approaches uniformity. The transport coefficient describing the diffusion thermoeffect must be equal to the coefficient describing thermal diffusion, according to the reciprocal relations central to the thermodynamics of irreversible processes.

Kinetic theory of gases

The aim of kinetic theory is to account for the properties of gases in terms of the forces between the molecules, assuming that their motions are described by the laws of mechanics (usually classical Newtonian mechanics, although quantum mechanics is needed in some cases). The present discussion focuses on dilute ideal gases, in which molecular collisions of at most two bodies are of primary importance. Only the simplest theories are treated here in order to avoid obscuring the fundamental physics with complex mathematics.

IDEAL GAS

The ideal gas equation of state can be deduced by calculating the pressure as caused by molecular impacts on a

container wall. The internal energy and Dalton's law of partial pressures also emerge from this calculation, along with some free-molecule phenomena. The calculation is significant because it is basically the same one used to explain all dilute-gas phenomena.

Pressure. Newton's second law of motion can be stated in not-so-familiar form as impulse equals change in momentum, where impulse is force multiplied by the time during which it acts. A molecule experiences a change in momentum when it collides with a container wall: during the collision an impulse is imparted by the wall to the molecule that is equal and opposite to the impulse imparted by the molecule to the wall. This is required by Newton's third law. The sum of the impulses imparted by all the molecules to the wall is, in effect, the pressure. Consider a system of molecules of mass m traveling with a velocity v in an enclosed container. In order to arrive at an expression for the pressure, a calculation will be made of the impulse imparted to one of the walls by a single impact, followed by a calculation of how many impacts occur on that wall during a time t. Although the molecules are moving in all directions, only those with a component of velocity toward the wall can collide with it; call this component v_z, where z represents the direction directly toward the wall. Not all molecules have the same v_z, of course; perhaps only N_z out of a total of N molecules do. To find the total pressure, the contributions from molecules with all different values of v_z must be summed. A molecule approaches the wall with an initial momentum mv_z, and after impact it moves away from the wall with an equal momentum in the opposite direction, $-mv_z$. Thus, the total change in momentum is $mv_z - (-mv_z) = 2mv_z$, which is equal to the total impulse imparted to the wall.

Molecule-wall collisions

The number of impacts on a small area A of the wall in time t is equal to the number of molecules that reach the wall in time t. Since the molecules are traveling at speed v_z, only those within a distance $v_z t$ and moving toward the wall will reach it in that time. Thus, the molecules that are traveling toward the wall and are within a volume $Av_z t$ will strike the area A of the wall in time t. On the average, half of the molecules in this volume will be moving toward the wall. If N_z molecules with speed component v_z are present in the total volume V, then $(1/2)(N_z/V)(A)(v_z t)$ molecules in the collision volume will hit, and each one contributes an impulse of $2mv_z$. The total impulse in time t is therefore $(1/2)(N_z/V)(A)(v_z t)(2mv_z) = (N_z/V)(mv_z^2)(At)$, which is equal to Ft, where F is the force on the wall due to the impacts. Equating these two expressions, the time factor t cancels out. Since pressure is defined as the force per unit area (F/A), it follows that the contribution to the pressure from the molecules with speed v_z is thus $(N_z/V)mv_z^2$. Because there are different values of v_z^2 for different molecules, the average value, denoted $\overline{v_z^2}$, is used to take into account the contributions from all the molecules. The pressure is thus given as $p = (N/V)m\overline{v_z^2}$.

Since the molecules are in random motion, this result is independent of the choice of axis. For any choice of (x, y, z) axes, the magnitude of the velocity is $v^2 = v_x^2 + v_y^2 + v_z^2$ (which is just the Pythagorean theorem in three dimensions), and taking the average gives $\overline{v^2} = \overline{v_x^2} + \overline{v_y^2} + \overline{v_z^2}$. The gas is in equilibrium, so it must appear the same in any direction, and the average velocities are therefore the same in all directions—*i.e.*, $\overline{v_x^2} = \overline{v_y^2} = \overline{v_z^2}$; thus $\overline{v^2} = 3\overline{v_z^2}$. When the value $(1/3)\overline{v^2}$ is substituted for $\overline{v_z^2}$ in the expression for pressure, the following equation is obtained:

Average velocity

$$p = \frac{1}{3}\frac{N}{V}m\overline{v^2}, \quad \text{or} \quad pV = \frac{1}{3}Nm\overline{v^2}. \tag{17}$$

To rewrite this in molar units, N is set equal to nN_0—*i.e.*, the product of the number of moles n and Avogadro's number N_0—to give

$$pv = \frac{1}{3}M\overline{v^2}, \tag{18}$$

where $M = N_0 m$ is the molecular weight of the gas and v is the volume per mole (V/n). Since the ideal gas equation of state relates pressure, molar volume, and temperature as $pv = RT$, the temperature T must be related to the average kinetic energy of the molecules as

$$\frac{1}{2}M\overline{v^2} = \frac{3}{2}RT. \tag{19}$$

This expression is often written in molecular (rather than molar) terms as $(1/2)[m\overline{v^2}] = (3/2)kT$, where $k = R/N_0$ is called Boltzmann's constant. If the gas is a mixture, the foregoing calculation shows that the impacts of the different species are simply added separately, and Dalton's law of partial pressures follows directly.

The energy law given as equation (16) also follows from equation (19): the kinetic energy of translational motion per mole is $(3/2)RT$. Any energy residing in the internal motions of the individual molecules is simply carried separately without contributing to the pressure.

Average molecular speeds can be calculated from the results of kinetic theory in terms of the so-called root-mean-square speed v_{rms}. The v_{rms} is the square root of the average of the squares of the speeds of the molecules: $(\overline{v^2})^{1/2}$. From equation (19) the v_{rms} is $(3RT/M)^{1/2}$. At 20° C the value for air $(M = 29)$ is 502 m/s, a result very close to the rough estimate of 5×10^2 m/s given above.

Molecule-molecule collisions were not considered in the calculation of the expression for pressure even though many such collisions occur. Such collisions could be ignored because they are elastic; *i.e.*, linear momentum is conserved in the collision, provided that no external forces act. Two molecules therefore continue to carry the same momentum to the wall even if they collide with one another before striking it. The ideal gas equation of state remains valid as the density is decreased, even holding for a free-molecule gas. The equation eventually fails as the density is increased, however, because other molecules exert forces and change the rate of collisions with the walls.

It was not until the mid- to late 19th century that kinetic theory was successfully applied to such calculations as gas pressure. Such notable scientists as Sir Isaac Newton and John Dalton had believed that gas pressure was caused by repulsions between molecules that pushed them against the container walls. For many reasons, the kinetic theory had overshadowed such static theories (and others such as vortex theories) by about 1860. It was not until 1875, however, that Maxwell actually proved that a static theory was in conflict with experiment.

Early static gas theory

Effusion. Consider the system described above in the calculation of gas pressure, but with the area A in the container wall replaced with a small hole. The number of molecules that escape through the hole in time t is equal to $(1/2)(N/V)\overline{v_z}(At)$. In this case, collisions between molecules are significant, and the result holds only for tiny holes in very thin walls (as compared to the mean free path), so that a molecule that approaches near the hole will get through without colliding with another molecule and being deflected away. The relationship between $\overline{v_z}$ and the average speed $\bar{v}$ is rather straightforward: $\overline{v_z} = (1/2)\bar{v}$.

If the rates for two different gases effusing through the same hole are compared, starting with the same gas density each time, it is found that much more light gas escapes than heavy gas and that more gas escapes at a high temperature than at a low temperature, other things being equal. In particular,

$$\frac{\text{effusion rate of gas 1}}{\text{effusion rate of gas 2}} = \frac{\overline{v_1}}{\overline{v_2}} = \left(\frac{m_2}{m_1}\right)^{1/2}\left(\frac{T_1}{T_2}\right)^{1/2}. \tag{20}$$

The last step follows from the energy formula, $(1/2)m\overline{v^2} = (3/2)kT$, where $(\overline{v^2})^{1/2}$ is approximated to be $\bar{v}$, even though $\overline{v^2}$ and $(\bar{v})^2$ actually differ by a numerical factor near unity (namely, $3\pi/8$). This result was discovered experimentally in 1846 by Graham for the case of constant temperature and is known as Graham's law of effusion. It can be used to measure molecular weights, to measure the vapour pressure of a material with a low vapour pressure, or to calculate the rate of evaporation of molecules from a liquid or solid surface.

Graham's law of effusion

Thermal transpiration. Suppose that two containers of the same gas but at different temperatures are connected by a tiny hole and that the gas is brought to a steady state. If the hole is small enough and the gas density is low enough that only effusion occurs, the equilibrium pressure will be greater on the high-temperature side. But, if the

initial pressures on both sides are equal, gas will flow from the low-temperature side to the high-temperature side to cause the high-temperature pressure to increase. The latter situation is called thermal transpiration, and the steady-state result is called the thermomolecular pressure difference. These results follow simply from the effusion formula if the ideal gas law is used to replace N/V with p/T:

$$\frac{\text{effusion rate from container 1}}{\text{effusion rate from container 2}} = \frac{p_1}{p_2}\left(\frac{T_2}{T_1}\right)^{1/2}. \tag{21}$$

When a steady state is reached, the effusion rates are equal, and thus

$$\frac{p_1}{p_2} = \left(\frac{T_1}{T_2}\right)^{1/2}. \tag{22}$$

This phenomenon was first investigated experimentally by Osborne Reynolds in 1879 in Manchester, Eng. Errors can result if a gas pressure is measured in a vessel at very low or very high temperature by connecting it via a fine tube to a manometer at room temperature. A continuous circulation of gas can be produced by connecting the two containers with another tube whose diameter is large compared with the mean free path. The pressure difference drives gas through this tube by viscous flow. A heat engine based on this circulating flow unfortunately has a low efficiency.

Viscosity. The kinetic-theory explanation of viscosity can be simplified by examining it in qualitative terms. Viscosity is caused by the transfer of momentum between two planes sliding parallel to one another but at different rates, and this momentum is transferred by molecules moving between the planes. Molecules from the faster plane move to the slower plane and tend to speed it up, while molecules from the slower plane travel to the faster plane and tend to slow it down. This is the mechanism by which one plane experiences the drag of the other. A simple analogy is two mail trains passing each other, with workers throwing mailbags between the trains. Every time a mailbag from the fast-moving train lands on the slow one, it imparts its momentum to the slow train, speeding it up a little; likewise each mailbag from the slow train that lands on the fast one slows it down a bit.

If the trains are too far apart, the mailbags cannot be passed between them. Similarly, the planes of a gas must be only about a mean free path apart in order for molecules to pass between them without being deflected by collisions. If one uses this approach, a simple calculation can be carried out, much as in the case of the gas pressure, with the result that

$$\eta = a\frac{N}{V}\bar{v}lm, \tag{23}$$

where a is a numerical constant of order unity, the term $(N/V)\bar{v}l$ is a measure of the number of molecules contained in a small counting cylinder, and the mass m is a measure of the momentum carried between the sliding planes. The cross-sectional area of the counting cylinder and the relative speed of the sliding planes do not appear in the equation because they cancel one another when the drag force is divided by the area and speed of the planes in order to find η.

It can now be seen why η is independent of gas density or pressure. The term (N/V) in equation (23) is the number of carriers of momentum, but l measures the number of collisions that interfere with these carriers and is inversely proportional to (N/V). The two effects exactly cancel each other. Viscosity increases with temperature because the average velocity $\bar{v}$ does; that is, momentum is carried more quickly when the molecules move faster. Although $\bar{v}$ increases as $T^{1/2}$, η increases somewhat faster because the mean free path also increases with temperature, since it is harder to deflect a fast molecule than a slow one. This feature depends explicitly on the forces between the molecules and is difficult to calculate accurately, as is the value of the constant a, which turns out to be close to 1/2.

Viscosity of mixtures

The behaviour of the viscosity of a mixture can also be explained by the foregoing calculation. In a mixture of a light gas and a viscous heavy gas, both types of molecules have the same average energy; however, most of the momentum is carried by the heavy molecules, which are therefore the main contributors to the viscosity. The light molecules are rather ineffective in deflecting the heavy molecules, so that the latter continue to carry virtually as much momentum as they would in the absence of light molecules. The addition of a light gas to a heavy gas therefore does not reduce the viscosity substantially and may in fact increase it because of the small extra momentum carried by the light molecules. The viscosity will eventually decrease when there are only a few heavy molecules remaining in a large sea of light molecules.

The main dependence of η on the molecular mass is through the product $\bar{v}m$ in equation (23), which varies as $m^{1/2}$ since $\bar{v}$ varies as $1/m^{1/2}$. Owing to this effect, heavy gases tend to be more viscous than light gases, but this tendency is compensated for to some degree by the behaviour of l, which tends to be smaller for heavy molecules because they are usually larger than light molecules and therefore more likely to collide. The often confusing connection between viscosity and molecular weight can thus be accounted for by equation (23).

Finally, in a free-molecule gas there are no collisions with other molecules to impede the transport of momentum, and the viscosity thus increases linearly with pressure or density until the number of collisions becomes great enough so that the viscosity assumes the constant value given by equation (23). The nonideal behaviour of the gas that accompanies further increases in density eventually leads to an increase in viscosity, and the viscosity of an extremely dense gas becomes much like that of a liquid.

Thermal conductivity. The kinetic-theory explanation of heat conduction is similar to that for viscosity, but in this case the molecules carry net energy from a region of higher energy (*i.e.*, temperature) to one of lower energy (temperature). Internal molecular motions must be accounted for because, though they do not transport momentum, they do transport energy. Monatomic gases, which carry only their kinetic energy of translational motion, are the simplest case. The resulting expression for thermal conductivity is

$$\lambda = a'\frac{N}{V}\bar{v}l\left(\frac{3}{2}k\right). \tag{24}$$

Heat capacity

which has the same basic form as equation (23) for viscosity, with $(3k/2)$ replacing m. The $(3k/2)$ is the heat capacity per molecule and is the conversion factor from an energy difference to a temperature difference.

It can be shown from equation (24) that the independence of density and the increase with temperature is the same for thermal conductivity as it is for viscosity. The dependence on molecular mass is different, however, with λ varying as $1/m^{1/2}$ owing to the factor $\bar{v}$. Thus, light gases tend to be better conductors of heat than are heavy gases, and this tendency is usually augmented by the behaviour of l.

The behaviour of the thermal conductivity of mixtures may be qualitatively explained. Adding heavy gas to light gas reduces the thermal conductivity because the heavy molecules carry less energy and also interfere with the energy transport of the light molecules.

The similar behaviour of λ and η suggests that their ratio might provide information about the constants a and a'. The ratio of a'/a is given as

$$\frac{\lambda}{\eta}\frac{m}{(3k/2)} = \frac{a'}{a}. \tag{25}$$

Although simple theory suggests that this ratio should be about one, both experiment and more refined theory give a value close to 5/2. This means that molecules do not "forget" their past history in every collision, but some persistence of their precollision velocities occurs. Molecules transport both energy and momentum from a somewhat greater distance than just one mean free path, but this distance is greater for energy than for momentum. This is plausible, for molecules with higher kinetic energies might be expected to have greater persistences.

Attempts to calculate the constants a and a' by tracing collision histories to find the "persistence of velocities" have not met with much success. The molecular "mem-

ory" fades slowly, too many previous collisions have to be traced, and the calculations become almost hopelessly complicated. A different theoretical approach is needed, which was finally supplied about 1916–17 independently by Enskog and Chapman. Their theory also shows that the same value of l applies to both η and λ, a fact that is not obvious in the simple theory described here.

The thermal conductivity of polyatomic molecules is accounted for by simply adding on a contribution for the energy carried by the internal molecular motions:

$$\lambda = a'\left(\frac{N}{V}\right)\bar{v}l\left(\frac{3}{2}k\right) + a''\left(\frac{N}{V}\right)\bar{v}lc_{int}, \tag{26}$$

where c_{int} is the contribution of the internal motions to the heat capacity (per molecule) and is easily found by subtracting $(3k/2)$ from the total measured heat capacity. As might be expected, the constant a'' is only about half as large as a'.

The pressure or density dependence of λ must be similar to that of η—an initial linear increase in the free-molecule region, followed by a constant value in the dilute-gas region and finally an increase in the dense-fluid region.

Difficulties in applying simple theory

Diffusion and thermal diffusion. Both of these properties present difficulties for the simple mean free path version of kinetic theory. In the case of diffusion it must be argued that collisions of the molecules of species 1 with other species 1 molecules do not inhibit the interdiffusion of species 1 and 2, and similarly for 2–2 collisions. If this is not assumed, the calculated value of the diffusion coefficient for the 1–2 gas pair, D_{12}, depends strongly on the mixture composition instead of being virtually independent of it, as is shown by experiment. The neglect of 1–1 and 2–2 collisions can be rationalized by noting that the flow of momentum is not disturbed by such like-molecule collisions owing to the conservation of momentum, but it can be contended that the argument was simply invented to make the theory agree with experiment. A more charitable view is that the experimental results demonstrate that collisions between like molecules have little affect on D_{12}. It is one of the triumphs of the accurate kinetic theory of Enskog and Chapman that this result clearly emerges.

If 1–1 and 2–2 collisions are ignored, a simple calculation gives a result much like those for η and λ:

$$D_{12} = a_{12}\bar{v}_{12}l_{12}, \tag{27}$$

where a_{12} is a numerical constant, $\bar{v}_{12}$ is an average relative speed for 1–2 collisions given by $\bar{v}_{12}^2 = (1/2)(\bar{v}_1^2 + \bar{v}_2^2)$, and l_{12} is a mean free path for 1–2 collisions that is inversely proportional to the total molecular number density, $(N_1 + N_2)/V$. Thus, D_{12} is inversely proportional to gas density or pressure, unlike η and λ, but the concentration difference is proportional to pressure, with the two effects canceling one another, as pointed out previously. The actual transport of molecules is therefore independent of pressure. The numerical value of a_{12}, as obtained by refined calculations, is close to 3/5.

The pressure dependence of pD_{12} should be qualitatively similar to that of η and λ—an initial linear increase in the free-molecule region, a constant value in the dilute-gas region, and finally an increase in the dense-fluid region.

Thermal diffusion presents special difficulties for kinetic theory. The transport coefficients η, λ, and D_{12} are always positive regardless of the nature of the intermolecular forces that produce the collisions—the mere existence of collisions suffices to account for their important features. The transport coefficient that describes thermal diffusion, however, depends critically on the nature of the intermolecular forces and the collisions and can be positive, negative, or zero. Its dependence on composition is also rather complicated. There have been a number of attempts to explain thermal diffusion with a simple mean free path model, but none has been satisfactory. No simple physical explanation of thermal diffusion has been devised, and recourse to the accurate, but complicated, kinetic theory is necessary.

Boltzmann equation. The simple mean free path description of gas transport coefficients accounts for the major observed phenomena, but it is quantitatively unsatisfactory with respect to two major points: the values of numerical constants such as a, a', a'', and a_{12} and the description of the molecular collisions that define a mean free path. Indeed, collisions remain a somewhat vague concept except when they are considered to take place between molecules modeled as hard spheres. Improvement has required a different, somewhat indirect, and more mathematical approach through a quantity called the velocity distribution function. This function describes how molecular velocities are distributed on the average: a few very slow molecules, a few very fast ones, and most near some average value—namely, $v_{rms} = (\bar{v^2})^{1/2} = (3kT/2)^{1/2}$. If this function is known, all gas properties can be calculated by using it to obtain various averages. For example, the average momentum carried in a certain direction would give the viscosity. The velocity distribution for a gas at equilibrium was suggested by Maxwell in 1859 and is represented by the familiar bell-shaped curve that describes the normal, or Gaussian, distribution of random variables in large populations. Attempts to support more definitively this result and to extend it to nonequilibrium gases led to the formulation of the Boltzmann equation, which describes how collisions and external forces cause the velocity distribution to change. This equation is difficult to solve in any general sense, but some progress can be made by assuming that the deviations from the equilibrium distribution are small and are proportional to the external influences that cause the deviations, such as temperature, pressure, and composition differences. Even the resulting simpler equations remained unsolved for nearly 50 years until the work of Enskog and Chapman, with a single notable exception. The one case that was solvable dealt with molecules that interact with forces that fall off as the fifth power of their separation (*i.e.*, as $1/r^5$), for which Maxwell found an exact solution. Unfortunately, thermal diffusion happens to be exactly zero for molecules subject to this force law, so that phenomenon was missed.

Velocity distribution function

It was later discovered that it is possible to use the solutions for the $1/r^5$ Maxwell model as a starting point and then calculate successive corrections for more general interactions. Although the calculations quickly increase in complexity, the improvement in accuracy is rapid, unlike the persistence-of-velocities corrections applied in mean free path theory. This refined version of kinetic theory is now highly developed, but it is quite mathematical and is not described here.

DEVIATIONS FROM THE IDEAL MODEL

Deviations from ideal gas behaviour occur both at low densities, where molecule-surface collisions become important, and at high densities, where a description in terms of only two-body collisions becomes inadequate. The low-density case can be handled in principle by including both molecule-surface and molecule-molecule collisions in the Boltzmann equation. Since this branch of the subject is now quite advanced and mathematical in character, only the high-density case will be discussed here.

Equation of state. To a first approximation, molecule-molecule collisions do not affect the ideal gas equation of state, $pv = RT$, but real gases at nonzero densities show deviations from this equation that are due to interactions among the molecules. Ever since the great advance made by van der Waals in 1873, an accurate universal formula relating p, v, and T has been sought. No completely satisfactory equation of state has been found, though important advances occurred in the 1970s and '80s. The only rigorous theoretical result available is an infinite-series expansion in powers of $1/v$, known as the virial equation of state:

Virial equation of state

$$\frac{pv}{RT} = 1 + \frac{B(T)}{v} + \frac{C(T)}{v^2} + \cdots, \tag{28}$$

where $B(T)$, $C(T)$, . . . are called the second, third, . . . virial coefficients and depend only on the temperature and the particular gas. The virtue of this equation is that there is a rigorous connection between the virial coefficients and intermolecular forces, and experimental values of $B(T)$ were an early source (and still a useful one) of quantitative information on intermolecular forces. The drawback of the virial equation of state is that it is an infinite series

and becomes essentially useless at high densities, which in practice are those greater than about the critical density. Also, the equation is wanting in that it does not predict condensation.

The most practical approaches to the equation of state for real fluids remain the versions of the principle of corresponding states first proposed by van der Waals.

Transport properties. Despite many attempts, there is still no satisfactory theory of the transport properties of dense fluids. Even the extension of the Boltzmann equation to include collisions of more than two bodies is not entirely clear. An important advance was made in 1921 by Enskog, but it is restricted to hard spheres and has not been extended to real molecules except in an empirical way to fit experimental measurements.

Attempts to develop a virial type of expansion in $1/v$ for the transport coefficients have failed in a surprising way. A formal theory was formulated, but, when the virial coefficients were evaluated for the tractable case of hard spheres, an infinite result was obtained for the coefficient of the $1/v^2$ term. This is a signal that a virial expansion is not accurate in a mathematical sense, and subsequent research showed that the error arose from a neglected term of the form $(1/v^2)\ln(1/v)$. It remains unknown how many similar problematic mathematical terms exist in the theory. Transport coefficients of dense fluids are usually described by some empirical extension of the Enskog hard-sphere theory or more commonly by some version of a principle of corresponding states. Much work clearly remains to be done. (E.A.M.)

PLASMA STATE

The plasma state of matter is unique like the solid, liquid, and gaseous states and is often considered the fourth state of matter. A plasma is an electrically conducting medium in which there are nearly equal numbers of positive and negative charges. The negative charge is usually carried by electrons, each of which has one unit of negative charge. The positive charge is typically carried by atoms or molecules that are missing those same electrons. In some rare but interesting cases, electrons missing from one type of atom or molecule become attached to another component, resulting in a plasma containing both positive and negative ions. The most extreme case of this type occurs when small but macroscopic dust particles become charged in a state referred to as a dusty plasma. The uniqueness of the plasma state is due to the importance of electric and magnetic forces that act on a plasma in addition to such forces as gravity that affect all forms of matter. Since these electromagnetic forces can act at large distances, a plasma will act collectively much like a fluid even when the particles seldom collide with one another.

Nearly all the visible matter in the universe exists in the plasma state, occurring predominantly in this form in the Sun and stars and in interplanetary and interstellar space. Auroras, lightning, and welding arcs are also plasmas; plasmas exist in neon and fluorescent tubes, in the crystal structure of metallic solids, and in many other phenomena and objects. The Earth itself is immersed in a tenuous plasma called the solar wind and is surrounded by a dense plasma called the ionosphere.

A plasma may be produced in the laboratory by heating a gas to an extremely high temperature, which causes such vigorous collisions between its atoms and molecules that electrons are ripped free, yielding the requisite electrons and ions. A similar process occurs inside stars. In space the dominant plasma formation process is photoionization, wherein photons from sunlight or starlight are absorbed by an existing gas, causing electrons to be emitted. Since the Sun and stars shine continuously, virtually all the matter becomes ionized in such cases, and the plasma is said to be fully ionized. This need not be the case, however, for a plasma may be only partially ionized. A completely ionized hydrogen plasma, consisting solely of electrons and protons (hydrogen nuclei), is the most elementary plasma.

The modern concept of the plasma state is of recent origin, dating back only to the early 1950s. Its history is interwoven with many disciplines. Three basic fields of study made unique early contributions to the development of plasma physics as a discipline: electric discharges, magnetohydrodynamics (in which a conducting fluid such as mercury is studied), and kinetic theory.

Interest in electric-discharge phenomena may be traced back to the beginning of the 18th century, with three English physicists—Michael Faraday in the 1830s and Joseph John Thomson and John Sealy Edward Townsend at the turn of the 19th century—laying the foundations of the present understanding of the phenomena. Irving Langmuir introduced the term plasma in 1923 while investigating electric discharges. In 1929 he and Lewi Tonks, another physicist working in the United States, used the term to designate those regions of a discharge in which certain periodic variations of the negatively charged electrons could occur. They called these oscillations plasma oscillations, their behaviour suggesting that of a jellylike substance. Not until 1952, however, when two other American physicists, David Bohm and David Pines, first considered the collective behaviour of electrons in metals as distinct from that in ionized gases, was the general applicability of the concept of a plasma fully appreciated.

The collective behaviour of charged particles in magnetic fields and the concept of a conducting fluid are implicit in magnetohydrodynamic studies, the foundations of which were laid in the early and middle 1800s by Faraday and André-Marie Ampère of France. Not until the 1930s, however, when new solar and geophysical phenomena were being discovered, were many of the basic problems of the mutual interaction between ionized gases and magnetic fields considered. In 1942 Hannes Alfvén, a Swedish physicist, introduced the concept of magnetohydrodynamic waves. This contribution, along with his further studies of space plasmas, led to Alfvén's receipt of the Nobel Prize for Physics in 1970.

These two separate approaches—the study of electric discharges and the study of the behaviour of conducting fluids in magnetic fields—were unified by the introduction of the kinetic theory of the plasma state. This theory states that plasma, like gas, consists of particles in random motion, whose interactions can be through long-range electromagnetic forces as well as via collisions. In 1905 the Dutch physicist Hendrik Antoon Lorentz applied the kinetic equation for atoms (the formulation by the Austrian physicist Ludwig Eduard Boltzmann) to the behaviour of electrons in metals. Various physicists and mathematicians in the 1930s and '40s further developed the plasma kinetic theory to a high degree of sophistication. Since the early 1950s interest has increasingly focused on the plasma state itself. Space exploration, the development of electronic devices, a growing awareness of the importance of magnetic fields in astrophysical phenomena, and the quest for controlled thermonuclear (nuclear fusion) power reactors all have stimulated such interest. Many problems remain unsolved in space plasma physics research, owing to the complexity of the phenomena. For example, descriptions of the solar wind must include not only equations dealing with the effects of gravity, temperature, and pressure as needed in atmospheric science but also the equations of the Scottish physicist James Clerk Maxwell, which are needed to describe the electromagnetic field.

Kinetic theory

Just as a lightweight cork in water will bob up and down about its rest position, any general displacement of light electrons as a group with respect to the positive ions in a plasma leads to the oscillation of the electrons as a whole about an equilibrium state. In the case of the cork, the restoring force is provided by gravity; in plasma oscillations, it is provided by the electric force. These movements are the plasma oscillations that were studied by Langmuir and Tonks. Analogously, just as buoyancy effects guide water waves, plasma oscillations are related to waves in the electron component of the plasma called

Langmuir waves. Wavelike phenomena play a critical role in the behaviour of plasmas.

The time τ required for an oscillation of this type is the most important temporal parameter in a plasma. The main spatial parameter is the Debye length, h, which is the distance traveled by the average thermal electron in time $\tau/2\pi$. A plasma can be defined in terms of these parameters as a partially or fully ionized gas that satisfies the following criteria: (1) a constituent electron may complete many plasma oscillations before it collides with either an ion or one of the other heavy constituents, (2) inside each sphere with a radius equal to the Debye length, there are many particles, and (3) the plasma itself is much larger than the Debye length in every dimension.

Another important temporal parameter is the time between collisions of particles. In any gas, separate collision frequencies are defined for collisions between all different particle types. The total collision frequency for a particular species is the weighted sum of all the separate frequencies.

Elastic and inelastic collisions

Two basic types of collision may occur: elastic and inelastic. In an elastic collision, the total kinetic energy of all the particles participating in the collision is the same before and after the event. In an inelastic collision, a fraction of the kinetic energy is transferred to the internal energy of the colliding particles. In an atom, for example, the electrons have certain allowed (discrete) energies and are said to be bound. During a collision, a bound electron may be excited—that is, raised from a low to a high energy state. This can occur, however, only by the expenditure of kinetic energy and only if the kinetic energy exceeds the difference between the two energy states. If the energy is sufficient, a bound electron may be excited to such a high level that it becomes a free electron, and the atom is said to be ionized; the minimum, or threshold, energy required to free an electron is called the ionization energy. Inelastic collisions may also occur with positive ions unless all the electrons have been stripped away. In general, only collisions of electrons and photons (quanta of electromagnetic radiation) with atoms and ions are significant in these inelastic collisions; ionization by a photon is called photoionization.

A molecule has additional discrete energy states, which may be excited by particle or photon collisions. At sufficiently high energies of interaction, the molecule can dissociate into atoms or into atoms and atomic ions. As in the case of atoms, collision of electrons and photons with molecules may cause ionization, producing molecular ions. In general, the reaction rate for inelastic collisions is similar to that of chemical reactions. At sufficiently high temperatures, the atoms are stripped of all electrons and become bare atomic nuclei. Finally, at temperatures of about 1,000,000 K or greater, nuclear reactions can occur—another form of inelastic collisions. When such reactions lead to the formation of heavier elements, the process is called thermonuclear fusion; mass is transmuted, and kinetic energy is gained instead of lost.

All sources of energy now existing on the Earth can be traced in one way or another to the nuclear fusion reactions inside the Sun or some long-extinct star. In such energy sources, gravity controls and confines the fusion process. The high temperatures required for the nuclear fusion reactions that take place in a hydrogen, or thermonuclear, bomb are attained by first igniting an atomic bomb, which produces a fission chain reaction. One of the great challenges of humankind is to create these high temperatures in a controlled manner and to harness the energy of nuclear fusion. This is the great practical goal of plasma physics—to produce nuclear fusion on the Earth. Confinement schemes devised by scientists use magnetic fields or the inertia of an implosion to guide and control the hot plasma.

Basic plasma physics

PLASMA FORMATION

Apart from solid-state plasmas, such as those in metallic crystals, plasmas do not usually occur naturally at the surface of the Earth. For laboratory experiments and technological applications, plasmas therefore must be produced artificially. Because the atoms of such alkalies as potassium, sodium, and cesium possess low ionization energies, plasmas may be produced from these by the direct application of heat at temperatures of about 3,000 K. In most gases, however, before any significant degree of ionization is achieved, temperatures in the neighbourhood of 10,000 K are required. A convenient unit for measuring temperature in the study of plasmas is the electron volt (eV), which is the energy gained by an electron in vacuum when it is accelerated across one volt of electric potential. The temperature, W, measured in electron volts is given by $W = T/12{,}000$ when T is expressed in kelvins. The temperatures required for self-ionization thus range from 2.5 to 8 electron volts, since such values are typical of the energy needed to remove one electron from an atom or molecule.

Artificial production of plasmas

Because all substances melt at temperatures far below that level, no container yet built can withstand an external application of the heat necessary to form a plasma; therefore, any heating must be supplied internally. One technique is to apply an electric field to the gas to accelerate and scatter any free electrons, thereby heating the plasma. This type of ohmic heating is similar to the method in which free electrons in the heating element of an electric oven heat the coil. Because of their small energy loss in elastic collisions, electrons can be raised to much higher temperatures than other particles. For plasma formation a sufficiently high electric field must be applied, its exact value depending on geometry and the gas pressure. The electric field may be set up via electrodes or by transformer action, in which the electric field is induced by a changing magnetic field. Laboratory temperatures of about 10,000,000 K, or 8 kiloelectron volts (keV), with electron densities of about 10^{19} per cubic metre have been achieved by the transformer method. The temperature is eventually limited by energy losses to the outside environment. Extremely high temperatures, but relatively low-density plasmas, have been produced by the separate injection of ions and electrons into a mirror system (a plasma device using a particular arrangement of magnetic fields for containment). Other methods have used the high temperatures that develop behind a wave that is moving much faster than sound to produce what is called a shock front; lasers have also been employed.

Natural plasma heating and ionization occur in analogous ways. In a lightning-induced plasma, the electric current carried by the stroke heats the atmosphere in the same manner as in the ohmic heating technique described above. In solar and stellar plasmas the heating is internal and caused by nuclear fusion reactions. In the solar corona, the heating occurs because of waves that propagate from the surface into the Sun's atmosphere, heating the plasma much like shock-wave heating in laboratory plasmas. In the ionosphere, ionization is accomplished not through heating of the plasma but rather by the flux of energetic photons from the Sun. Far-ultraviolet rays and X rays from the Sun have enough energy to ionize atoms in the Earth's atmosphere. Some of the energy also goes into heating the gas, with the result that the upper atmosphere, called the thermosphere, is quite hot. These processes protect the Earth from energetic photons much as the ozone layer protects terrestrial life-forms from lower-energy ultraviolet light. The typical temperature 300 kilometres above the Earth's surface is 1,200 K, or about 0.1 eV. Although it is quite warm compared with the surface of the Earth, this temperature is too low to create self-ionization. When the Sun sets with respect to the ionosphere, the source of ionization ceases, and the lower portion of the ionosphere reverts to its nonplasma state. Some ions, in particular singly charged oxygen (O^+), live long enough that some plasma remains until the next sunrise. In the case of an aurora, a plasma is created in the nighttime or daytime atmosphere when beams of electrons are accelerated to hundreds or thousands of electron volts and smash into the atmosphere.

METHODS OF DESCRIBING PLASMA PHENOMENA

The behaviour of a plasma may be described at different levels. If collisions are relatively infrequent, it is useful

to consider the motions of individual particles. In most plasmas of interest, a magnetic field exerts a force on a charged particle only if the particle is moving, the force being at right angles to both the direction of the field and the direction of particle motion. In a uniform magnetic field (B), a charged particle gyrates about a line of force. The centre of the orbit is called the guiding centre. The particle may also have a component of velocity parallel to the magnetic field and so traces out a helix in a uniform magnetic field. If a uniform electric field (E) is applied at right angles to the direction of the magnetic field, the guiding centre drifts with a uniform velocity of magnitude equal to the ratio of the electric to the magnetic field (E/B), at right angles to both the electric and magnetic fields. A particle starting from rest in such fields follows the same cycloidal path a dot on the rim of a rolling wheel follows. Although the "wheel" radius and its sense of rotation vary for different particles, the guiding centre moves at the same E/B velocity, independent of the particle's charge and mass. Should the electric field change with time, the problem would become even more complex. If, however, such an alternating electric field varies at the same frequency as the cyclotron frequency (*i.e.,* the rate of gyration), the guiding centre will remain stationary, and the particle will be forced to travel in an ever-expanding orbit. This phenomenon is called cyclotron resonance and is the basis of the cyclotron particle accelerator.

Cyclotron resonance

The motion of a particle about its guiding centre constitutes a circular current. As such, the motion produces a dipole magnetic field not unlike that produced by a simple bar magnet. Thus, a moving charge not only interacts with magnetic fields but also produces them. The direction of the magnetic field produced by a moving particle, however, depends both on whether the particle is positively or negatively charged and on the direction of its motion. If the motion of the charged particles is completely random, the net associated magnetic field is zero. On the other hand, if charges of different sign have an average relative velocity (*i.e.,* if an electric current flows), then a net magnetic field over and above any externally applied field exists. The magnetic interaction between charged particles is therefore of a collective, rather than of an individual, particle nature.

At a higher level of description than that of the single particle, kinetic equations of the Boltzmann type are used. Such equations essentially describe the behaviour of those particles about a point in a small-volume element, the particle velocities lying within a small range about a given value. The interactions with all other velocity groups, volume elements, and any externally applied electric and magnetic fields are taken into account. In many cases, equations of a fluid type may be derived from the kinetic equations; they express the conservation of mass, momentum, and energy per unit volume, with one such set of equations for each particle type.

DETERMINATION OF PLASMA VARIABLES

The basic variables useful in the study of plasma are number densities, temperatures, electric and magnetic field strengths, and particle velocities. In the laboratory and in space, both electrostatic (charged) and magnetic types of sensory devices called probes help determine the magnitudes of such variables. With the electrostatic probe, ion densities, electron and ion temperatures, and electrostatic potential differences can be determined. Small search coils and other types of magnetic probes yield values for the magnetic field; and from Maxwell's electromagnetic equations the current and charge densities and the induced component of the electric field may be found. Interplanetary spacecraft have carried such probes to nearly every planet in the solar system, revealing to scientists such plasma phenomena as lightning on Jupiter and the sounds of Saturn's rings and radiation belts. In the early 1990s, signals were being relayed to the Earth from several spacecraft approaching the edge of the plasma boundary to the solar system, the heliopause.

In the laboratory the absorption, scattering, and excitation of neutral and high-energy ion beams are helpful in determining electron temperatures and densities; in general, the refraction, reflection, absorption, scattering, and interference of electromagnetic waves also provide ways to determine these same variables. This technique has also been employed to remotely measure the properties of the plasmas in the near-space regions of the Earth using the incoherent scatter radar method. The largest single antenna is at the National Astronomy and Ionosphere Center at Arecibo in Puerto Rico. It has a circumference of 305 metres and was completed in 1963. It is still used to probe space plasmas to distances of 3,000 kilometres. The method works by bouncing radio waves from small irregularities in the electron gas that occur owing to random thermal motions of the particles. The returning signal is shifted slightly from the transmitted one—because of the Doppler-shift effect—and the velocity of the plasma can be determined in a manner similar to the way in which the police detect a speeding car. Using this method, the wind speed in space can be found, along with the temperature, density, electric field, and even the types of ions present. In geospace the appropriate radar frequencies are in the range of 50 to 1,000 megahertz (MHz), while in the laboratory, where the plasma densities and plasma frequencies are higher, microwaves and lasers must be used.

Aside from the above methods, much can be learned from the radiation generated and emitted by the plasma itself; in fact, this is the only means of studying cosmic plasma beyond the solar system. The various spectroscopic techniques covering the entire continuous radiation spectrum determine temperatures and identify such nonthermal sources as those pulses producing synchrotron radiations.

WAVES IN PLASMAS

The waves most familiar to people are the buoyancy waves that propagate on the surfaces of lakes and oceans and break onto the world's beaches. Equally familiar, although not necessarily recognized as waves, are the disturbances in the atmosphere that create what is referred to as the weather. Wave phenomena are particularly important in the behaviour of plasmas. In fact, one of the three criteria for the existence of a plasma is that the particle-particle collision rate be less than the plasma-oscillation frequency. This in turn implies that the collective interactions that control the plasma gas depend on the electric and magnetic field effects as much as, or more so than, simple collisions. Since waves are able to propagate, the possibility exists for force fields to act at large distances from the point where they originated.

Ordinary fluids can support the propagation of sound (acoustic) waves, which involve pressure, temperature, and velocity variations. Electromagnetic waves can propagate even in a vacuum but are slowed down in most cases by the interaction of the electric fields in the waves with the charged particles bound in the atoms or molecules of the gas. Although it is important for a complete description of electromagnetic waves, such an interaction is not very strong. In a plasma, however, the particles react in concert with any electromagnetic field (*e.g.,* as in an electromagnetic wave) as well as with any pressure or velocity field (*e.g.,* as in a sound wave). In fact, in a plasma sound wave the electrons and ions become slightly separated owing to their difference in mass, and an electric field builds up to bring them back together. The result is called an ion acoustic wave. This is just one of the many types of waves that can exist in a plasma. The brief discussion that follows touches on the main types in order of increasing wave-oscillation frequency.

At the lowest frequency are Alfvén waves, which require the presence of a magnetic field to exist. In fact, except for ion acoustic waves, the existence of a background magnetic field is required for any wave with a frequency less than the plasma frequency to occur in a plasma. Most natural plasmas are threaded by a magnetic field, and laboratory plasmas often use a magnetic field for confinement, so this requirement is usually met, and all types of waves can occur.

Alfvén waves

Alfvén waves are analogous to the waves that occur on the stretched string of a guitar. In this case, the string represents a magnetic field line. When a small magnetic field disturbance takes place, the field is bent slightly, and

the disturbance propagates in the direction of the magnetic field. Since any changing magnetic field creates an electric field, an electromagnetic wave results. Such waves are the slowest and have the lowest frequencies of any known electromagnetic waves. For example, the solar wind streams out from the Sun with a speed greater than either electromagnetic (Alfvén) or sound waves. This means that, when the solar wind hits the Earth's outermost magnetic field lines, a shock wave results to "inform" the incoming plasma that an obstacle exists, much like the shock wave associated with a supersonic airplane. The shock wave travels toward the Sun at the same speed but in the opposite direction as the solar wind, so it appears to stand still with respect to the Earth. Because there are almost no particle-particle collisions, this type of collisionless shock wave is of great interest to space plasma physicists who postulate that similar shocks occur around supernovas and in other astrophysical plasmas. On the Earth's side of the shock wave, the heated and slowed solar wind interacts with the Earth's atmosphere via Alfvén waves propagating along the magnetic field lines.

The turbulent surface of the Sun radiates large-amplitude Alfvén waves, which are thought to be responsible for heating the corona to 1,000,000 K. Such waves can also produce fluctuations in the solar wind, and, as they propagate through it to the Earth, they seem to control the occurrence of magnetic storms and auroras that are capable of disrupting communication systems and power grids on the planet.

Types of wave motion

Two fundamental types of wave motion can occur: longitudinal, like a sound or ion acoustic wave, in which particle oscillation is in a direction parallel to the direction of wave propagation; and transverse, like a surface water wave, in which particle oscillation is in a plane perpendicular to the direction of wave propagation. In all cases, a wave may be characterized by a speed of propagation (u), a wavelength (λ), and a frequency (ν) related by an expression in which the velocity is equal to the product of the wavelength and frequency, namely, $u = \lambda\nu$. The Alfvén wave is a transverse wave and propagates with a velocity that depends on the particle density and the magnetic field strength. The velocity is equal to the magnetic flux density (B) divided by the square root of the mass density (ρ) times the permeability of free space (μ_0)—that is to say, $B/\sqrt{\mu_0\rho}$. The ion acoustic wave is a longitudinal wave and also propagates parallel to the magnetic field at a speed roughly equal to the average thermal velocity of the ions. Perpendicular to the magnetic field a different type of longitudinal wave called a magnetosonic wave can occur.

In these waves the plasma behaves as a whole, and the velocity is independent of wave frequency. At higher frequencies, however, the separate behaviour of ions and electrons causes the wave velocities to vary with direction and frequency. The Alfvén wave splits into two components, referred to as the fast and slow Alfvén waves, which propagate at different frequency-dependent speeds. At still higher frequencies these two waves (called the electron cyclotron and ion cyclotron waves, respectively) cause electron and cyclotron resonances (synchronization) at the appropriate resonance frequencies. Beyond these resonances, transverse wave propagation does not occur at all until frequencies comparable to and above the plasma frequency are reached.

At frequencies between the ion and electron gyrofrequencies lies a wave mode called a whistler. This name comes from the study of plasma waves generated by lightning. When early researchers listened to natural radio waves by attaching an antenna to an audio amplifier, they heard a strange whistling sound. The whistle occurs when the electrical signal from lightning in one hemisphere travels along the Earth's magnetic field lines to the other hemisphere. The trip is so long that some waves (those at higher frequencies) arrive first, resulting in the generation of a whistlelike sound. These natural waves were used to probe the region of space around the Earth before spacecraft became available. Such a frequency-dependent wave velocity is called wave dispersion because the various frequencies disperse with distance.

The speed of an ion acoustic wave also becomes dispersive at high frequencies, and a resonance similar to electron plasma oscillations occurs at a frequency determined by electrostatic oscillations of the ions. Beyond this frequency no sonic wave propagates parallel to a magnetic field until the frequency reaches the plasma frequency, above which electroacoustic waves occur. The wavelength of these waves at the critical frequency (ω_p) is infinite, the electron behaviour at this frequency taking the form of the plasma oscillations of Langmuir and Tonks. Even without particle collisions, waves shorter than the Debye length are heavily damped—*i.e.*, their amplitude decreases rapidly with time. This phenomenon, called Landau damping, arises because some electrons have the same velocity as the wave. As they move with the wave, they are accelerated much like a surfer on a water wave and thus extract energy from the wave, damping it in the process.

Containment

Magnetic fields are used to contain high-density, high-temperature plasmas because such fields exert pressures and tensile forces on the plasma. An equilibrium configuration is reached only when at all points in the plasma these pressures and tensions exactly balance the pressure from the motion of the particles. A well-known example of this is the pinch effect observed in specially designed equipment. If an external electric current is imposed on a cylindrically shaped plasma and flows parallel to the plasma axis, the magnetic forces act inward and cause the plasma to constrict, or pinch. An equilibrium condition is reached in which the temperature is proportional to the square of the electric current. This result suggests that any temperature may be achieved by making the electric current sufficiently large, the heating resulting from currents and compression. In practice, however, since no plasma can be infinitely long, serious energy losses occur at the ends of the cylinder; also, major instabilities develop in such a simple configuration. Suppression of such instabilities has been one of the major efforts in laboratory plasma physics and in the quest to control the nuclear fusion reaction.

A useful way of describing the confinement of a plasma by a magnetic field is by measuring containment time (τ_c), or the average time for a charged particle to diffuse out of the plasma; this time is different for each type of configuration. Various types of instabilities can occur in plasma. These lead to a loss of plasma and a catastrophic decrease in containment time. The most important of these is called magnetohydrodynamic instability. Although an equilibrium state may exist, it may not correspond to the lowest possible energy. The plasma, therefore, seeks a state of lower potential energy, just as a ball at rest on top of a hill (representing an equilibrium state) rolls down to the bottom if perturbed; the lower energy state of the plasma corresponds to a ball at the bottom of a valley. In seeking the lower energy state, turbulence develops, leading to enhanced diffusion, increased electrical resistivity, and large heat losses. In toroidal geometry, circular plasma currents must be kept below a critical value called the Kruskal-Shafranov limit, otherwise a particularly violent instability consisting of a series of kinks may occur. Although a completely stable system appears to be virtually impossible, considerable progress has been made in devising systems that eliminate the major instabilities. Temperatures on the order of 10,000,000 K at densities of 10^{19} particles per cubic metre and containment times as high as $^1/_{50}$ of a second have been achieved.

Kruskal-Shafranov limit

APPLICATIONS OF PLASMAS

The most important practical applications of plasmas lie in the future, largely in the field of power production. The major method of generating electric power has been to use heat sources to convert water to steam, which drives turbogenerators. Such heat sources depend on the combustion of fossil fuels, such as coal, oil, and natural gas, and fission processes in nuclear reactors. A potential source of heat might be supplied by a fusion reactor, with a basic element of deuterium-tritium plasma; nuclear fusion collisions between those isotopes of hydrogen would release large amounts of energy to the kinetic energy of the reaction products (the neutrons and the nuclei of hydrogen and helium atoms). By absorbing those products in a

surrounding medium, a powerful heat source could be created. To realize a net power output from such a generating station—allowing for plasma radiation and particle losses and for the somewhat inefficient conversion of heat to electricity—plasma temperatures of about 100,000,000 K and a product of particle density times containment time of about 10^{20} seconds per cubic metre are necessary. For example, at a density of 10^{20} particles per metre cubed, the containment time must be one second. Such figures are yet to be reached, although there has been much progress.

In general, there are two basic methods of eliminating or minimizing end losses from an artificially created plasma: the production of toroidal plasmas and the use of magnetic mirrors (see ATOMS: *Nuclear fusion*). A toroidal plasma is essentially one in which a plasma of cylindrical cross section is bent in a circle so as to close on itself. For such plasmas to be in equilibrium and stable, however, special magnetic fields are required, the largest component of which is a circular field parallel to the axis of the plasma. In addition, a number of turbulent plasma processes must be controlled to keep the system stable. In 1991 a machine called the JET (Joint European Torus) achieved the state known as ignition, a first step toward a practical fusion device.

Besides generating power, a fusion reactor might desalinate seawater. Approximately two-thirds of the world's land surface is uninhabited, with one-half of this area being arid. The use of both giant fission and fusion reactors in the large-scale evaporation of seawater could make irrigation of such areas economically feasible. Another possibility in power production is the elimination of the heat–steam–mechanical energy chain. One suggestion depends on the dynamo effect. If a plasma moves perpendicular to a magnetic field, an electromotive force, according to Faraday's law, is generated in a direction perpendicular to both the direction of flow of the plasma and the magnetic field. This dynamo effect can drive a current in an external circuit connected to electrodes in the plasma, and thus electric power may be produced without the need for steam-driven rotating machinery. This process is referred to as magnetohydrodynamic (MHD) power generation and has been proposed as a method of extracting power from certain types of fission reactors. Such a generator powers the auroras as the Earth's magnetic field lines tap electrical current from the MHD generator in the solar wind.

Current from the dynamo effect

The inverse of the dynamo effect, called the motor effect, may be used to accelerate plasma. By pulsing cusp-shaped magnetic fields in a plasma, for example, it is possible to achieve thrusts proportional to the square of the magnetic field. Motors based on such a technique have been proposed for the propulsion of craft in deep space. They have the advantage of being capable of achieving large exhaust velocities, thus minimizing the amount of fuel carried.

A practical application of plasma involves the glow discharge that occurs between two electrodes at pressures of one-thousandth of an atmosphere or thereabouts. Such glow discharges are responsible for the light given off by neon tubes and such other light sources as fluorescent lamps, which operate by virtue of the plasmas they produce in electric discharge. The degree of ionization in such plasmas is usually low, but electron densities of 10^{16} to 10^{18} electrons per cubic metre can be achieved with an electron temperature of 100,000 K. The electrons responsible for current flow are produced by ionization in a region near the cathode, with most of the potential difference between the two electrodes occurring there. This region does not contain a plasma, but the region between it and the anode (*i.e.*, the positive electrode) does.

Use in radio switching devices

Other applications of the glow discharge include electronic switching devices; it and similar plasmas produced by radio-frequency techniques can be used to provide ions for particle accelerators and act as generators of laser beams. As the current is increased through a glow discharge, a stage is reached when the energy generated at the cathode is sufficient to provide all the conduction electrons directly from the cathode surface, rather than from gas between the electrodes. Under this condition the large cathode potential difference disappears, and the plasma column contracts. This new state of electric discharge is called an arc. Compared with the glow discharge, it is a high-density plasma and will operate over a large range of pressures. Arcs are used as light sources for welding, in electronic switching, for rectification of alternating currents, and in high-temperature chemistry. Running an arc between concentric electrodes and injecting gas into such a region causes a hot, high-density plasma mixture called a plasma jet to be ejected. It has many chemical and metallurgical applications.

Natural plasmas

EXTRATERRESTRIAL FORMS

It has been suggested that the universe originated as a violent explosion about 10 billion years ago and initially consisted of a fireball of completely ionized hydrogen plasma. Irrespective of the truth of this, there is little matter in the universe now that does not exist in the plasma state. The observed stars are composed of plasmas, as are interstellar and interplanetary media and the outer atmospheres of planets. Scientific knowledge of the universe has come primarily from studies of electromagnetic radiation emitted by plasmas and transmitted through them and, since the 1960s, from space probes within the solar system.

In a star the plasma is bound together by gravitational forces, and the enormous energy it emits originates in thermonuclear fusion reactions within the interior. Heat is transferred from the interior to the exterior by radiation in the outer layers, where convection is of greater importance. In the vicinity of a hot star, the interstellar medium consists almost entirely of completely ionized hydrogen, ionized by the star's ultraviolet radiation. Such regions are referred to as H II regions. The greater proportion by far of interstellar medium, however, exists in the form of neutral hydrogen clouds referred to as H I regions. Because the heavy atoms in such clouds are ionized by ultraviolet radiation (or photoionized), they also are considered to be plasmas, although the degree of ionization is probably only one part in 10,000. Other components of the interstellar medium are grains of dust and cosmic rays, the latter consisting of very high-energy atomic nuclei completely stripped of electrons. The almost isotropic velocity distribution of the cosmic rays may stem from interactions with waves of the background plasma.

Magnetic fields in space

Throughout this universe of plasma there are magnetic fields. In interstellar space magnetic fields are about 5×10^{-6} gauss (a unit of magnetic field strength) and in interplanetary space 5×10^{-5} gauss, whereas in intergalactic space they could be as low as 10^{-9} gauss. These values are exceedingly small compared with the Earth's surface field of about 5×10^{-1} gauss. Although small in an absolute sense, these fields are nevertheless gigantic, considering the scales involved. For example, to simulate interstellar phenomena in the laboratory, fields of about 10^{15} gauss would be necessary. Thus, these fields play a major role in nearly all astrophysical phenomena. On the Sun the average surface field is in the vicinity of 1 to 2 gauss, but magnetic disturbances arise, such as sunspots, in which fields of between 10 and 1,000 gauss occur. Many other stars are also known to have magnetic fields.

Table 8: Various Natural Plasmas and Their Electron Densities and Temperatures

plasma	n_e (per cu m)	T_e (K)
Sun		
Centre	10^{31}	1.5×10^7
Photosphere	10^{20}	4,200
Chromosphere	10^{17}–10^{20}	5×10^5
Corona	10^{13}	1.5×10^6
Solar wind (near Earth)	5×10^6	4×10^5
Interstellar space		
H II regions	10^6	10^4
H I regions	10^2	100–125
Intergalactic space	1	3?
Earth		
Outer magnetosphere	10^6–10^7	10^4
Plasmasphere	10^9–10^{10}	10^4
Ionosphere	10^{11}–10^{12}	250–3,000
Metals	10^{28}	10^4

Field strengths of 10^{-3} gauss are associated with various extragalactic nebulae from which synchrotron radiation has been observed.

SOLAR-TERRESTRIAL FORMS

The visible region of the Sun is the photosphere (see Table 8), with its radiation being about the same as the continuum radiation from a 5,000 K blackbody. Lying above the photosphere is the chromosphere, which is observed by the emission of line radiation from various atoms and ions. Outside the chromosphere, the corona expands into the ever-blowing solar wind (see below), which on passing through the planetary system eventually encounters the interstellar medium. The corona can be seen in spectacular fashion when the Moon eclipses the bright photosphere (see Figure 43). During the times in which sunspots are greatest in number (called the sunspot maximum), the corona is very extended and the solar wind is fierce. Sunspot activity waxes and wanes with roughly an 11-year cycle. During the mid-1600s and early 1700s, sunspots virtually disappeared for a period known as the Maunder minimum. This time coincided with the Little Ice Age in Europe, and much conjecture has arisen about the possible effect of sunspots on climate. Periodic variations similar to that of sunspots have been observed in tree rings and lake-bed sedimentation. If real, such an effect is important because it implies that the Earth's climate is fragile.

In 1958 the American astrophysicist Eugene Parker showed that the equations describing the flow of plasma in the Sun's gravitational field had one solution that allowed the gas to become supersonic and to escape the Sun's pull. The solution was much like the description of a rocket nozzle in which the constriction in the flow is analogous to the effect of gravity. Parker predicted the Sun's atmosphere would behave just as this particular solar-wind solution predicts rather than according to the solar-breeze solutions suggested by others. The interplanetary satellite probes of the 1960s proved his solution to be correct.

Solar wind

The solar wind is a collisionless plasma made up primarily of electrons and protons and carries an outflow of matter moving at supersonic and super-Alfvénic speed. The wind takes with it an extension of the Sun's magnetic field, which is frozen into the highly conducting fluid. In the region of the Earth, the wind has an average speed of 400 kilometres per second; and, when it encounters the planet's magnetic field, a shock front develops, the pressures acting to compress the field on the side toward the Sun and elongate it on the nightside (in the Earth's lee away from the Sun). The Earth's magnetic field is therefore confined to a cavity called the magnetosphere, into which the direct entry of the solar wind is prohibited. This cavity extends for about 10 Earth radii on the Sun's side and about 1,000 Earth radii on the nightside.

Inside this vast magnetic field a region of circulating plasma is driven by the transfer of momentum from the solar wind. Plasma flows parallel to the solar wind on the edges of this region and back toward the Earth in its interior. The resulting system acts as a secondary magnetohydrodynamic generator (the primary one being the solar wind itself). Both generators produce potential on the order of 100,000 volts. The solar-wind potential appears across the polar caps of the Earth, while the magnetospheric potential appears across the auroral oval. The latter is the region of the Earth where energetic electrons and ions precipitate into the planet's atmosphere, creating a spectacular light show. This particle flux is energetic enough to act as a new source of plasmas even when the Sun is no longer shining. The auroral oval becomes a good conductor; and large electric currents flow along it, driven by the potential difference across the system. These currents commonly are on the order of 1,000,000 amperes.

The plasma inside the magnetosphere is extremely hot (1–10 million K) and very tenuous (1–10 particles per cubic centimetre). The particles are heated by a number of interesting plasma effects, the most curious of which is the auroral acceleration process itself. A particle accelerator that may be the prototype for cosmic accelerators throughout the universe is located roughly one Earth radius above the auroral oval and linked to it by all-important magnetic field lines. In this region the auroral electrons are boosted by a potential difference on the order of three to six kilovolts, most likely created by an electric field parallel to the magnetic field lines and directed away from the Earth. Such a field is difficult to explain because magnetic

Figure 43: The solar corona as seen from La Paz, Mex., during the July 11, 1991, total eclipse. The corona is the source of the solar wind plasma that continuously bathes the Earth.

field lines usually act like nearly perfect conductors. The auroras occur on magnetic field lines that—if it were not for the distortion of the Earth's dipole field—would cross the equatorial plane at a distance of 6–10 Earth radii.

Closer to the Earth, within about 4 Earth radii, the planet wrests control of the system away from the solar wind. Inside this region the plasma rotates with the Earth, just as its atmosphere rotates with it. This system can also be thought of as a magnetohydrodynamic generator in which the rotation of the atmosphere and the ionospheric plasma in it create an electric field that puts the inner magnetosphere in rotation about the Earth's axis. Since this inner region is in contact with the dayside of the Earth where the Sun creates copious amounts of plasma in the ionosphere, the inner zone fills up with dense, cool plasma to form the plasmasphere. On a planet such as Jupiter, which has both a larger magnetic field and a higher rotation rate than the Earth, planetary control extends much farther from the surface.

The ionosphere

At altitudes below about 2,000 kilometres, the plasma is referred to as the ionosphere. Thousands of rocket probes have helped chart the vertical structure of this region of the atmosphere, and numerous satellites have provided latitudinal and longitudinal information. The ionosphere was discovered in the early 1900s when radio waves were found to propagate "over the horizon." If radio waves have frequencies near or below the plasma frequency, they cannot propagate throughout the plasma of the ionosphere and thus do not escape into space; they are instead either reflected or absorbed. At night the absorption is low since little plasma exists at the height of roughly 100 kilometres where absorption is greatest. Thus, the ionosphere acts as an effective mirror, as does the Earth's surface, and waves can be reflected around the entire planet much as in a waveguide. A great communications revolution was initiated by the wireless, which relied on radio waves to transmit audio signals. Development continues to this day with satellite systems that must propagate through the ionospheric plasma. In this case, the wave frequency must be higher than the highest plasma frequency in the ionosphere so that the waves will not be reflected away from the Earth.

The dominant ion in the upper atmosphere is atomic oxygen, while below about 200 kilometres molecular oxygen and nitric oxide are most prevalent. Meteor showers also provide large numbers of metallic atoms of elements such as iron, silicon, and magnesium, which become ionized in sunlight and last for long periods of time. These form vast ion clouds, which are responsible for much of the fading in and out of radio stations at night.

Noctilucent clouds

A more normal type of cloud forms at the base of the Earth's plasma blanket in the summer polar mesosphere regions. Located at an altitude of 85 kilometres, such a cloud is the highest on Earth and can be seen only when darkness has just set in on the planet. Hence, clouds of this kind have been called noctilucent clouds. They are thought to be composed of charged and possibly dusty ice crystals that form in the coldest portion of the atmosphere at a temperature of 120 K. This unusual medium has much in common with dusty plasmas in planetary rings and other cosmic systems. Noctilucent clouds have been increasing in frequency throughout the 20th century and may be a forerunner of global change.

High-energy particles also exist in the magnetosphere. At about 1.5 and 3.5 Earth radii from the centre of the planet, two regions contain high-energy particles. These regions are the Van Allen radiation belts, named after the American scientist James Van Allen, who discovered them using radiation detectors aboard early spacecraft. The charged particles in the belts are trapped in the mirror system formed by the Earth's magnetic dipole field.

Plasma can exist briefly in the lowest regions of the Earth's atmosphere. In a lightning stroke an oxygen-nitrogen plasma is heated at approximately 20,000 K with an ionization of about 20 percent, similar to that of a laboratory arc. Although the stroke is only a few centimetres thick and lasts only a fraction of a second, tremendous energies are dissipated. A lightning flash between the ground and a cloud, on the average, consists of four such strokes in rapid succession. At all times, lightning is occurring somewhere on the Earth, charging the surface negatively with respect to the ionosphere by roughly 200,000 volts, even far from the nearest thunderstorm. If lightning ceased everywhere for even one hour, the Earth would discharge. An associated phenomenon is ball lightning. There are authenticated reports of glowing, floating, stable balls of light several tens of centimetres in diameter occurring at times of intense electrical activity in the atmosphere. On contact with an object, these balls release large amounts of energy. Although lightning balls are probably plasmas, so far no adequate explanation of them has been given.

Lightning flashes and ball lightning

Considering the origins of plasma physics and the fact that the universe is little more than a vast sea of plasma, it is ironic that the only naturally occurring plasmas at the surface of the Earth besides lightning are those to be found in ordinary matter. The free electrons responsible for electrical conduction in a metal constitute a plasma. Ions are fixed in position at lattice points, and so plasma behaviour in metals is limited to such phenomena as plasma oscillations and electron cyclotron waves (called helicon waves) in which the electron component behaves separately from the ion component. In semiconductors, on the other hand, the current carriers are electrons and positive holes, the latter behaving in the material as free positive charges of finite mass. By proper preparation, the number of electrons and holes can be made approximately equal so that the full range of plasma behaviour can be observed.

The importance of magnetic fields in astrophysical phenomena has already been noted. It is believed that these

Figure 44: An image in visible light of the eastern United States and Canada, taken by the optical line scanner aboard the F9 satellite of the Defense Meteorological Satellite Program. The image was obtained on March 14, 1989, during a major magnetic storm. The white band stretching from Hudson Bay to Ohio is due to electron impact on the Earth's atmosphere that results in the creation of a dense plasma and the light emission called an aurora.

fields are produced by self-generating dynamos, although the exact details are still not fully understood. In the case of the Earth, differential rotation in its liquid conducting core causes the external magnetic dipole field (manifest as the North and South poles). Cyclonic turbulence in the liquid, generated by heat conduction and Coriolis forces (apparent forces accompanying all rotating systems, including the heavenly bodies), generates the dipole field from these loops. Over geologic time, the Earth's field occasionally becomes small and then changes direction, the North Pole becoming the South Pole and vice versa. During the times in which the magnetic field is small, cosmic rays can more easily reach the Earth's surface and may affect life forms by increasing the rate at which genetic mutations occur.

Similar magnetic-field generation processes are believed to occur in both the Sun and the Milky Way Galaxy. In the Sun the circular internal magnetic field is made observable by lines of force apparently breaking the solar surface to form exposed loops; entry and departure points are what are observed as sunspots. Although the exterior magnetic field of the Earth is that of a dipole, this is further modified by currents in both the ionosphere and magnetosphere. Lunar and solar tides in the ionosphere lead to motions across the Earth's field that produce currents, like a dynamo, that modify the initial field. The auroral oval current systems discussed earlier create even larger magnetic-field fluctuations. The intensity of these currents is modulated by the intensity of the solar wind, which also induces or produces other currents in the magnetosphere. Such currents taken together constitute the essence of a magnetic storm. An image of the eastern United States and Canada taken during a major magnetic storm is shown in Figure 44. (B.S.L./M.C.K.)

CLUSTERS

Atoms and molecules are the smallest forms of matter typically encountered under normal conditions and are in that sense the basic building blocks of the material world. As described in the previous section, there are phenomena, such as lightning and electric discharges of other kinds, that allow free electrons to be observed, but these are exceptional occurrences. It is of course in its gaseous state that matter is encountered at its atomic or molecular level; in gases each molecule is an independent entity, only occasionally and briefly colliding with another molecule or with a confining wall.

In contrast to the free-molecule character of gases, the condensed phases of matter—as liquids, crystalline solids, and glasses are called—depend for their properties on the constant proximity of all their constituent atoms. The extent to which the identities of the molecular constituents are maintained varies widely in these condensed forms of matter. Weakly bound solids, such as solid carbon dioxide (dry ice), or their liquid counterparts, such as liquid air or liquid nitrogen, are made up of molecules whose properties differ only slightly from the properties of the same molecules in gaseous form; such solids or liquids are simply molecules packed tightly enough to be in constant contact. These are called van der Waals solids or liquids, after Johannes D. van der Waals, the Dutch physicist who described the weak forces that just manage to hold these materials together if they are cold enough. In other solids, like diamond, graphite, silicon, or quartz, the individual atoms retain their identity, but there are no identifiable molecules in their structures. The forces between the constituent atoms are roughly as strong as the forces that hold atoms together in the strongly bound covalent molecules that make up most common substances. Negatively charged electrons act as a "glue" to hold the positively charged nuclei together and are more or less confined to the vicinity of the so-called home-base nuclei with which they are associated; they are not free to roam through the entire solid or liquid. These materials are said to be covalently bound and are electrical insulators. They are best described as neutral atoms held together by covalent bonds and are essentially one giant molecule.

Binding in condensed phases of matter

Another kind of bonding found in condensed matter is exhibited by sodium chloride, ordinary table salt, which is composed of positive sodium ions (Na^+) and negative chloride ions (Cl^-). Such ionic compounds are held together by the mutual attraction of the oppositely charged ions; because of their locations, these attractions are stronger than the repulsions of the ions with like charges. Each ion in an ionic crystal is surrounded by nearest neighbours of opposite charge. The consequence is that the binding energies of ionic compounds are large, comparable to those of strongly bound covalent substances.

Metallic bonding is another type of binding found in condensed matter. Electrons moving between the positive atomic cores (*i.e.*, the nuclei plus inner-shell, tightly bound electrons) form an electron cloud; the attractions between the positive cores and the negative charges that make up the cloud hold metals together. Metals differ from covalently bound insulators in that those electrons responsible for the cohesion of the metals move freely throughout the metal when given the slightest extra energy. For example, under the influence of the electric field produced in a copper wire when its ends are connected to the terminals of a battery, electrons move through the wire from the end connected to the battery's negative pole toward the end connected to its positive pole. An electric field applied to a metal generates an electric current, but the same electric field applied to a covalent insulator does not (see below *Comparison with other forms of matter*). The net binding forces between electrons and atomic cores of a metal are comparable in strength to those that hold ionic compounds together.

As mentioned above, liquids constitute a condensed or dense phase of matter, but their atomic arrangement differs from that of solids. In a liquid the constituent atoms are only slightly farther apart than they are in a solid, but that small difference is significant enough to allow the atoms or molecules that constitute a liquid to move around and to assume a full range of geometric configurations. Atoms of the same kind can trade places and can wander through the liquid by the random-walk process called diffusion. In general, materials that can form solids can also form liquids, but some, such as carbon dioxide, can only enter the liquid state under excess pressure. At least one substance, helium, can form a liquid while having no known solid form.

Diffusion of liquids

Materials that form solids and liquids can exhibit another form, one that may be solidlike or liquidlike but that has properties somewhat different from those of the bulk. This is the form of matter consisting of exceedingly small particles that are called clusters. Clusters are aggregates of atoms, molecules, or ions that adhere together under forces like those that bind the atoms, ions, or molecules of bulk matter; because of the manner in which they are prepared, clusters remain as tiny particles at least during the course of an experiment. There are clusters held together by van der Waals forces, by ionic forces, by covalent bonds, and by metallic bonds. Despite the similarity of the forces that bind both clusters and bulk matter, one of the fascinating aspects of clusters is that their properties differ from those of the corresponding bulk material; that characteristic affords the opportunity to learn about the properties of bulk matter by studying how, as the number of constituent particles increases, the properties of clusters evolve into those of bulk matter. For example, a cluster of 20 or 30 atoms typically has a melting point far lower than that of the corresponding bulk. The electrical properties of clusters also differ in some instances from those of the bulk matter: clusters of only a few atoms of mercury are insulators, held together by weak van der Waals forces, but clusters of hundreds of mercury atoms are metallic. One of the puzzles posed by clusters is the question of how properties of small clusters evolve with size into properties of bulk matter.

Comparison with other forms of matter

Clusters versus bulk matter

Several characteristics differentiate clusters from molecules and bulk matter. They differ from bulk matter, first and foremost, in size; whether three particles bound together constitute a cluster is a matter of choice and convention, but an aggregate of four or more atoms or molecules certainly comprises a cluster. Such a small cluster would differ markedly from bulk matter in almost all its properties. A second difference between clusters and bulk matter is the variability of the properties of clusters with the number of their constituent particles. The properties of a lump of bulk matter remain unchanged by the addition or subtraction of a few atoms or molecules, whereas the properties of a small cluster vary significantly and, in general, neither uniformly nor even in the same direction with a change in the number of constituent particles. Medium-size clusters have properties that vary smoothly with the number of constituent particles (denoted N), but their properties, such as the melting point, differ significantly from those of the corresponding bulk. Large clusters have properties that vary smoothly with N and clearly merge into those of their bulk counterparts. This distinction, while not extremely precise, is quite useful. For example, the average binding energies—that is, the average energy per constituent atom or molecule required to separate the particles from each other—vary widely with N for small clusters. The reason for this wide range is that clusters of certain values of N, known as magic numbers, can take on unusually stable geometric structures that yield large binding energies, while others with different small values of N have no especially stable forms and therefore only relatively low binding energies. The binding energies of medium-size clusters vary rather smoothly with N, but they are in general considerably lower than the binding energies of bulk matter. The most important reason for this trend is that in a body of bulk matter almost all the particles are in the interior, while in a cluster most of the particles are on the surface. In a cluster of 13 atoms of copper or argon, for example, 12 of the atoms are on the surface. In a cluster of 55 argon atoms, 42 atoms are on the surface, and, in a cluster of 137 argon atoms, 82 are on the surface. Surface atoms are bonded only to atoms in their own layer and to those directly beneath them, so they have fewer atoms holding them to the main body of matter, whether cluster or bulk, than do atoms in the interior. Hence, the average binding energies of atoms in clusters are normally considerably less than those of bulk matter.

An important difference between clusters, in particular small and medium-size clusters, and bulk solids is the structure that is assumed by their most stable form. Most bulk solids are crystalline. This means that their atomic structures consist of periodic lattices—*i.e.*, structures that repeat over and over so that every unit composed of a few neighbouring atoms is indistinguishable from other groups of atoms that have exactly the same arrangement. In a simple cubic crystal, for example, all the atoms lie at the corners of cubes (in fact at a point common to eight equivalent cubes), and all these lattice points are identical. Such structures are called periodic. Most clusters, by contrast, have structures that are not periodic; many have the form of icosahedrons, incomplete icosahedrons, or other polyhedral structures that cannot grow into periodic lattices. One of the challenging puzzles of cluster science is to explain how, as an aggregate grows, it transforms from a polyhedral cluster-type structure into a crystalline lattice-type structure.

Quantum mechanical considerations

Furthermore, some properties of clusters reflect their small size in more subtle ways that depend on quantum mechanical phenomena. These are generally much more pronounced in exceedingly small systems than in bulk or macroscopic samples. One such property is the nature of the energy levels occupied by the electrons. In a macroscopic sample the energies of the states available to an electron are, in principle, discrete but are merged into bands consisting of many energy levels. Within each band the intervals of energy between those discrete levels are too tiny to be discerned; only the gaps between the bands are large enough to be important because they correspond to ranges of energy that are forbidden to the electrons. In fact, it is the contrast in the mobility of electrons that differentiates insulators from electrical conductors. In even a very cold metal, only an infinitesimal amount of excess energy is required to promote a few electrons into the previously empty energy levels in which they can move freely throughout the material. If an electric field is applied to the metal, the negatively charged electrons move toward the positive pole of the field so that a net current flows in the metal. It is the motion of these electrons, driven by an applied field, that makes metals conductors of electricity. In an insulator the electrons fill all the energy levels up to the top of the highest-energy occupied band. This means that at least the full energy of the forbidden interval, called the band gap, must be imparted to any electron to promote it to an allowed state where it may travel readily through the material. In an insulator this is far more energy than is normally available, and so no electrons are in states that allow them to move freely; such materials cannot conduct electric currents.

Clusters containing only a small number of metal atoms have so few available quantum states for their electrons that these states must be considered discrete, not as components of a dense band of available states. In this sense, small clusters of metal atoms are like conventional molecules rather than like bulk metals. Medium-size clusters of metal atoms have electronic energy states that are

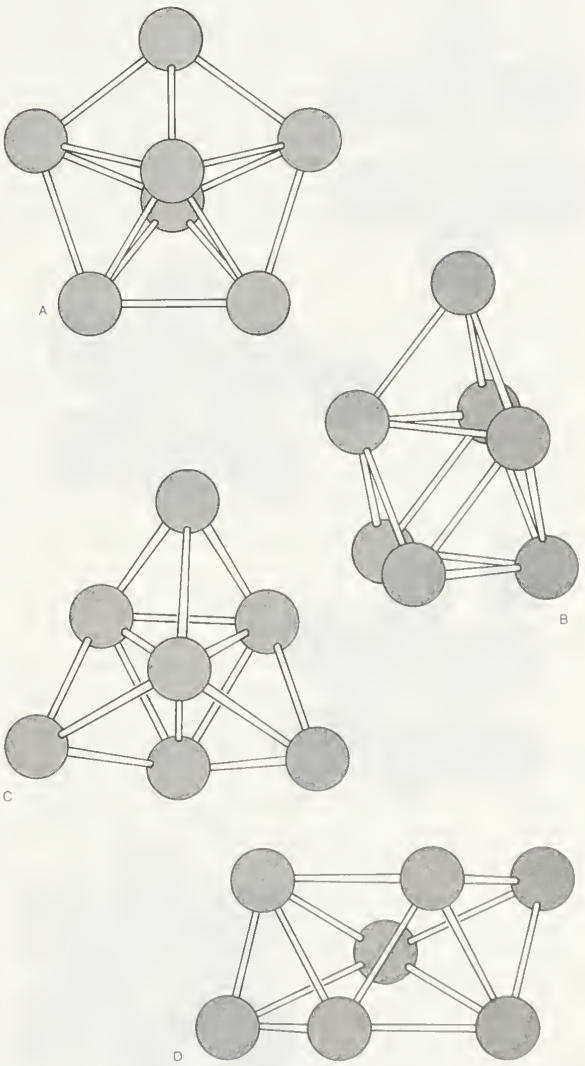

Figure 45: The four stable geometric structures of the seven-atom cluster of argon, in order of increasing energy: (A) A pentagonal bipyramid. (B) A regular octahedron with one face capped by the seventh atom. (C) A regular tetrahedron with three of its faces capped by other atoms. (D) A trigonal bipyramid with two of its faces capped by other atoms; although this has the highest energy of the four structures, it is very close in energy to the tricapped tetrahedron.

close enough together to be treated like the bands of bulk metals, but the conducting properties of these clusters are different from those of the bulk. Electrons driven by a constant electric field in a bulk metal can travel distances that are extremely long compared with atomic dimensions before they encounter any boundaries at the edges of the metal. Electrons in metal clusters encounter the boundaries of their cluster in a much shorter distance. Hence, metal clusters do not conduct electricity like bulk metals; if they are subjected to rapidly oscillating electric fields, such as those of visible, infrared, or microwave radiation, their "free" electrons are driven first one way and then back in the opposite direction over distances smaller than the dimensions of the cluster (see below *Physical properties*). If they are subjected to constant or low-frequency electric fields, such as the common 60-hertz fields that drive ordinary household currents, the electrons reach the boundaries of their clusters and can go no farther. Thus, the equivalent of conduction is not seen at low frequencies.

Clusters versus molecules

The manner in which clusters differ from molecules is more of a categorical nature than one of physical properties. Molecules have a definite composition and geometry; with few exceptions clusters can be made of any number of particles and may have any of several geometries. The four possible structures of a cluster of seven argon atoms are shown in Figure 45, and the lowest and next three higher-energy structures of a 13-atom cluster of argon are illustrated in Figure 46. The 13-atom cluster has the form of a regular icosahedron of 12 argon atoms around a central atom and is particularly stable.

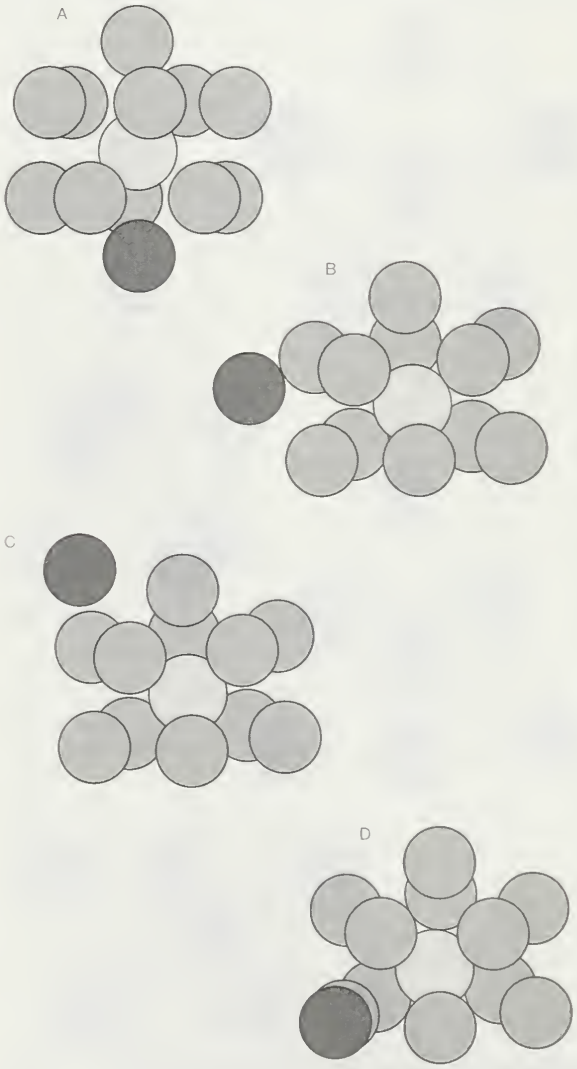

Figure 46: The four lowest-energy structures of the 13-atom cluster of argon: (A) The structure of lowest energy—the regular icosahedron of 12 atoms around a central atom. (B,C,D) The three structures, which have almost equal energy, formed by removing one of the 12 equivalent atoms from the 13-atom cluster in (A) from its shell and placing it into one of the three types of triangular faces in the resulting cluster.

Despite their multiplicity of structures, small clusters of fixed size, undergoing vibrations of small amplitude around a single geometry, are in most respects indistinguishable from molecules. If such clusters are given energy that is not great enough in magnitude to break them into separate parts, they may assume other geometries, alternating among these structural forms. This phenomenon is rarely seen with conventional molecules, but it is not unknown for energized molecules to exhibit more than one structure and to pass among them.

All in all, small clusters are much like molecules and are often considered to be molecules, while very large clusters are quite similar to bulk matter. The properties of clusters whose size is between these extremes may be like either or like neither.

Methods of study

Clusters can be studied by experiment, by theoretical analysis, and by simulation with computer-generated models. For several reasons they cannot be studied in the same manner as bulk matter. First, if individual clusters are allowed to coalesce into a mass, they will actually turn into bulk matter, so they must be kept separated. Second, it is desirable (but not always possible) to conduct experiments that distinguish the size and structure of each kind of cluster under observation. Because of these two considerations, experiments with clusters are usually more difficult than those with either specific molecules or bulk matter. Most of the difficulties arise from the same properties that make clusters interesting: the ease with which their sizes and compositions are varied and the variety of structures available for clusters of almost any given size.

Because of these difficulties, most experiments on clusters have been carried out with the clusters isolated in the gas phase; a few studies have been done with them in solution or in frozen matrices. Clusters can be prepared in the gas phase and then either studied in that form or captured into solvents or matrices or onto surfaces. They may be made by condensation of atoms or molecules or by direct blasting of matter from solids. In the most generally used method, a gas containing the gaseous cluster material is cooled by passing it under high pressure through a fine hole or slot. The expansion cools the gas rapidly from its initial temperature—usually room temperature but much higher if the cluster material is solid at room temperature—to a temperature not far above absolute zero. If, for example, argon gas is expanded in this way, it condenses into clusters if the pressure is not too high and the aperture is not too small; if the conditions are too extreme, the argon instead turns to snow and condenses.

Preparation of clusters

Inert gases are often used as the medium by which other materials, in a gaseous or vaporous state, are transported from the ovens or other sources where they have been gasified and through the jets that cool them and turn them into clusters. One especially popular and interesting method in which solids are vaporized is by the action of intense laser beams on solid surfaces. Often called ablation, this process is an effective means of vaporizing even highly refractory materials like solid carbon. The ablated material is then carried through the cooling jet by an inert gas such as helium or argon.

Once the clusters have been formed, they can be studied in a variety of ways. One of the first techniques was simply to ionize the clusters, either with ultraviolet radiation (usually from a laser) or by electron impact. The gaseous ionized clusters are accelerated by an electric field and then analyzed according to their masses (see ANALYSIS AND MEASUREMENT: *Mass spectrometry*); these results immediately reveal the number of atoms or molecules in the cluster. The analysis yields the distribution of the relative abundances of clusters of different sizes in the beam. If the experiment is done with considerable care, the abundance distribution corresponds to the true relative stabilities of the clusters of different sizes. However, like many experiments with clusters, these can either provide results consistent with the equilibrium conditions that re-

flect those relative stabilities, or they can give results that reflect the rates of the cluster-forming processes rather than the equilibrium characteristics, as the latter may take far longer to reach than the time required to form clusters. Some of the implications of the abundances found in such experiments are discussed below in the section *Structure and properties: Structure.*

Because of the conditions under which clusters are formed, their distributions contain many different sizes and, in some instances, different shapes. Because chemists seek to characterize clusters of a single size and geometry, the clusters must first be sorted on that basis. If the clusters carry charge, they can be separated according to size with a mass spectrometer that sorts charged particles with approximately the same energy according to their masses. This is usually done by deflecting the charged clusters or ions with an electric or magnetic field; the smaller the mass, the greater is the deflection. This is one of the most effective ways of preparing a beam of clusters of only a single selected mass. It does not eliminate the problem of multiple structures, however.

A technique that can sometimes be used to sort clusters according to their size and structure is a two-step process in which one cluster species at a time is excited with the light from a laser and is then ionized with light from a second laser. This process, called resonant two-photon ionization, is highly selective if the clusters being separated have moderately different absorption spectra. Since this is frequently the case, the method is quite powerful. As the experimenter varies the wavelength of the first exciting laser, a spectrum is produced that includes those wavelengths of light that excite the cluster. If the wavelength of the second ionizing laser is varied, the method also yields the ionization potential, which is the minimum energy that the photon in the ionizing beam must possess in order to knock an electron out of the cluster. Such data help to reveal the forces that bind the cluster together and give some indication of how the cluster will react with atoms, molecules, or other clusters.

A powerful tool for studying clusters is computer simulation of their behaviour. If the nature of the forces between the individual atoms or molecules in a cluster is known, then one can construct a computer model that represents the behaviour of those atoms or molecules by solving the equations of motion of the cluster. To describe the cluster in terms of classical mechanics, the Newtonian equations of motion are solved repeatedly—namely, force equals mass times acceleration, in which the forces depend on the instantaneous positions of all the particles. Hence, these equations are simultaneous, interlinked equations; there is one set of three (for the three instantaneous coordinates of each particle) for each atom or molecule. The results can take one of three forms: (1) the positions and coordinates of the atoms, given in tables, (2) the average properties of the entire cluster, or (3) animations. Tables are too cumbersome for most purposes, and specific average properties are frequently what the investigator seeks. Animated sequences show the same content as the tables but far more efficiently than extensive tables do. In fact, animations sometimes reveal considerably more than is expected by scientists.

It is also possible to construct computer models of clusters based on quantum mechanics instead of Newton's classical mechanics. This is especially appropriate for clusters of hydrogen and helium, because the small masses of their constituent atoms make them very quantumlike in the sense that they reveal the wavelike character that all matter exhibits according to quantum mechanics. The same kinds of data and inferences can be extracted from quantum mechanical calculations as from classical ones, but the preparation and visualization of animations for such clusters are much more demanding than their classical mechanical counterparts.

Structure and properties

STRUCTURE

The abundance distributions for several kinds of clusters show that there are certain sizes of clusters with exceptional stability, analogous to the exceptional stability of the atoms of the inert gases helium, neon, argon, krypton, and xenon and of the so-called magic number nuclei—*i.e.*, the sequence of unusually stable atomic nuclei beginning with the α-particle, or helium nucleus. Such unusual stability suggests that its interpretation should be associated with the closing of some kind of shell, or energy level. The overall structure that determines the cluster's stability is generally called its shell structure.

Stability of icosahedral structures

Clusters of atoms bound by van der Waals forces or by other simple forces that depend only on the distance between each pair of atoms have unusual stability when the cluster has exactly the number of atoms needed to form a regular icosahedron. The first three clusters in this series have, respectively, 13, 55, and 147 atoms. These are shown in Figure 47. In the 13-atom cluster, all but one of the atoms occupy equivalent sites. The 55-atom cluster in this series consists of a core—which is just the 13-atom icosahedron—plus 12 more atoms atop the 12 vertices of the icosahedron and 30 more atoms, one in the centre of each of the 30 edges of the icosahedron. The 147-atom cluster consists of a 55-atom icosahedral core, 12 more atoms at the vertices of the outermost shell, one atom in the centre of each of the 20 faces, and two atoms along each of the 30 edges between the vertices. The shell structure that provides special stabilities in this class of clusters is determined by the individual stabilities of the shells of the atoms themselves.

A different kind of extraordinary stability manifests itself in clusters of simple metal atoms. The shell structure for this class of clusters is determined by the electrons and the filling of those shells that have energy states available to the electrons. The numbers of electrons corresponding to closed electron shells in metal clusters are 8, 20, 40, 58, ... The electron structure can be modeled by supposing that the positively charged cores consisting of the protons and inner-shell electrons of all the cluster's atoms are smeared out into a continuous, attractive background,

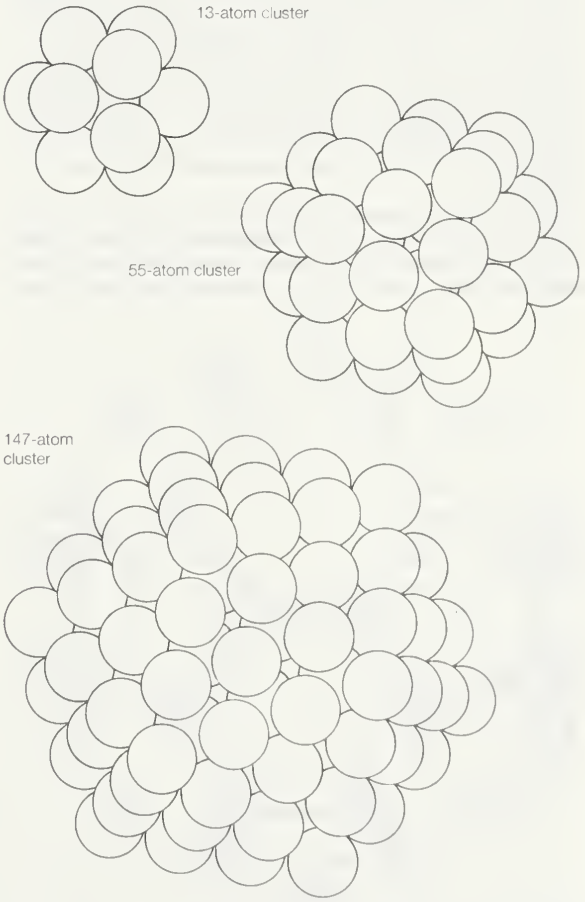

Figure 47: The first three complete icosahedral structures of 13, 55, and 147 particles. These are the structures taken on by clusters of 13, 55, and 147 atoms of neon, argon, krypton, and xenon, for example.

while the valence, or outer-shell, electrons are delocalized (*i.e.*, shared among all atoms in the cluster). The electron environment is much like a well or pit with a flat bottom and a moderately steep wall. The determination of the energy states available for electrons in such a simplified model system is relatively easy and gives a good description of clusters of more than about eight or nine alkali atoms—*i.e.*, lithium, sodium, potassium, rubidium, or cesium. The single valence, or outer-shell, electron of each alkali atom is treated explicitly, while all the others are considered part of the smeared-out core. Since each alkali atom has only one valence electron, the unusually stable clusters of alkalis consist of 8, 20, 40, . . . atoms, corresponding to major shell closings. This model is not as successful in treating metals such as aluminum, which have more than one valence electron.

Still another kind of particularly stable closed shell occurs in clusters sometimes called network structures. The best-known of these is C_{60}, the 60-atom cluster of carbon atoms. In this cluster the atoms occupy the sites of the 60 equivalent vertices of the soccer ball structure, which can be constructed by cutting off the 12 vertices of the icosahedron to make 12 regular 5-sided (regular pentagonal) faces. The icosahedron itself has 20 triangular faces; when its vertices are sliced off, the triangles become hexagons. The 12 pentagons share their edges with these 20 hexagonal faces. No two pentagons have any common edge in this molecule or cluster (C_{60} may be considered either). The resulting high-symmetry structure has been named buckminsterfullerene, after R. Buckminster Fuller, who advocated using such geometric structures in architectural design (see Figure 48).

Other network compounds of carbon are also known. To form a closed-shell structure, a network compound of carbon must have exactly 12 rings of 5 carbon atoms, but the number of rings of 6 carbon atoms is variable. Shells smaller than C_{60} have been discovered, but some of their constituent pentagons must share edges; this makes the smaller network compounds less stable than C_{60}. Shells larger than C_{60}, such as C_{70}, C_{76}, and C_{84}, are known and are relatively stable. Even tubes and "onions" of concentric layers of carbon shells have been reported in observations made with modern electron microscopes known as scanning tunneling microscopes. These devices are powerful enough to reveal images of extremely small clusters and even individual foreign atoms deposited on clean surfaces.

Fullerenes

The network compounds of carbon, which make up the class called fullerenes, form compounds with alkali and other metals. Some of these compounds of fullerenes combined with metals, such as K_3C_{60}, become superconductors at low temperatures; that is to say, they lose all resistance to electric current flow when they are cooled sufficiently. The class of network compounds as a group had been imagined from time to time, but only in the late 1980s were they realized in the laboratory and shown to have closed-shell network structures.

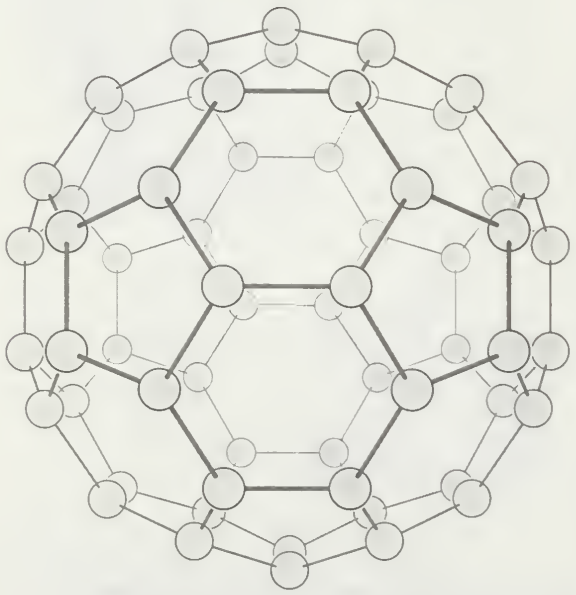

Figure 48: The structure of C_{60}, buckminsterfullerene. The geometry is that of a soccer ball with a carbon atom at each vertex (see text).

PHYSICAL PROPERTIES

Clusters share some of the physical properties of bulk matter, a few of which are rather surprising. Clusters of all substances except helium and possibly hydrogen are solidlike at low temperatures as expected. The atoms or molecules of a cluster remain close to their equilibrium positions, vibrating around these positions in moderately regular motions of small amplitude. This is characteristic of all solids; their atoms are constrained to stay roughly in the same position at all times. In a liquid or a gas, the atoms or molecules are free to wander through the space accessible to the substance. A gas or vapour has so much empty space relative to the volume occupied by the particles that the particles move almost unhindered, colliding only occasionally with other particles or with the walls of the container. A liquid is typically almost as dense as a solid but has some empty spaces into which the atoms or molecules can easily move. Hence, the particles of a liquid can diffuse with moderate ease. (Water is an exception; its density as a liquid is higher than its density as ice, because ice has an unusually open structure in comparison with most solids, and this open structure collapses when ice turns to water.) Clusters can be liquidlike if they are warm enough, but typically the temperatures at which clusters can become liquid are much lower than the melting points of the corresponding bulk solids. If temperatures are measured on the Kelvin scale, small clusters become liquidlike at temperatures of roughly half the bulk melting temperatures. For example, solid argon melts at approximately 80 K, while small clusters of argon become liquid at about 40 K.

Some clusters are expected to show a gradual transition from solidlike to liquidlike, appearing slushy in the temperature range between their solidlike and liquidlike zones. Other clusters are expected to show, as seen in computer simulations, distinct solidlike and liquidlike forms that qualitatively resemble bulk solids and liquids in virtually every aspect, even though they may exhibit quantitative differences from the bulk. Solid clusters, for example, show virtually no diffusion, but the particles of a liquid cluster can and do diffuse. The forces that hold a particle in place in a solid cluster are strong, comparable to those of a bulk solid; but those in a liquid cluster include, in addition to forces comparable in strength to those in solids, some forces weak enough to allow a particle to wander far from its home base and find new equilibrium positions. Those same weak forces are responsible for making a liquid cluster compliant; that is, weak forces allow the liquid to accommodate any new force, say, a finger inserted into water. Ice will not yield to such an intruding force, but when a finger is placed into liquid water, the water molecules move aside under the force of the finger. This is much like the behaviour of a bulk liquid. The greatest differences between bulk solids and liquids and solid and liquid clusters arise from the fact that a large fraction of the particles of a cluster are on its surface. As a result, the particle mobility that characterizes liquids and enables them to exhibit diffusion and physical compliance is enhanced in a cluster, for the cluster can easily expand by enlarging the spaces between particles and can also transfer particles from its interior to its surface, leaving vacancies that enhance the mobility of the interior particles. The large surface area, together with the curved shape of the cluster's surface, make it easier for particles to leave a cluster than to leave the flat surface of a bulk liquid or solid. An important consequence is that the vapour pressure of a cluster is higher than the vapour pressure of the corresponding bulk, and accordingly the boiling point of a liquid cluster—*i.e.*, the temperature at which the vapour pressure of a liquid is equal to the pressure of the surrounding atmosphere—is lower than that of the corresponding bulk liquid. The vapour pressure of

clusters decreases with increasing cluster size, while the boiling point increases.

Perhaps the greatest difference between clusters and bulk matter with regard to their transformation between solid and liquid is the nature of the equilibrium between two phases. Bulk solids can be in equilibrium with their liquid forms at only a single temperature for any given pressure or at only a single pressure for any given temperature. A graph of the temperatures and pressures along which the solid and liquid forms of any given substance are in equilibrium is called a coexistence curve. One point on the coexistence curve for ice and liquid water is 0° C and one atmosphere of pressure. A similar curve can be drawn for the coexistence of any two bulk phases, such as liquid and vapour; a point on the coexistence curve for liquid water and steam is 100° C and one atmosphere of pressure. Clusters differ sharply from bulk matter in that solid and liquid clusters of the same composition are capable of coexisting within a band of temperatures and pressures. At any chosen pressure, the proportion of liquid clusters to solid clusters increases with temperature. At low temperatures the clusters are solid, as described above. As the temperature is increased, some clusters transform from solid to liquid. If the temperature is raised further, the proportion of liquid clusters increases, passing through 50 percent, so that the mixture becomes predominantly liquid clusters. At sufficiently high temperatures all the clusters are liquid.

No cluster remains solid or liquid all the time; liquidlike clusters occasionally transform spontaneously into solidlike clusters and vice versa. The fraction of time that a particular cluster spends as a liquid is precisely the same as the fraction of clusters of that same type within a large collection that are liquid at a given instant. That is to say, the time average behaviour gives the same result as the ensemble average, which is the average over a large collection of identical objects. This equivalence is not limited to clusters; it is the well-known ergodic property that is expected of all but the simplest real systems.

Electric properties

Other significant physical properties of clusters are their electric, magnetic, and optical properties. The electric properties of clusters, such as their conductivity and metallic or insulating character, depend on the substance and the size of the cluster. Quantum theory attributes wavelike character to matter, a behaviour that is detectable only when matter is examined on the scale of atoms and electrons. At a scale of millimetres or even millionths of millimetres, the wavelengths of matter are too short to be observed. Clusters are often much smaller than that, with the important consequence that many are so small that when examined their electrons and electronic states can exhibit the wavelike properties of matter. In fact, quantum properties may play an important role in determining the electrical character of the cluster. In particular, as described previously, if a cluster is extremely small, the energy levels or quantum states of its electrons are not close enough together to permit the cluster to conduct electricity.

Moreover, an alternative way to view this situation is to recognize that a constant electric force (*i.e.*, the kind that drives a direct current) and an alternating force (the kind that generates alternating current) can behave quite differently in a cluster. Direct current cannot flow in an isolated cluster and probably cannot occur in a small cluster even if it is sandwiched between slabs of metal. The current flow is prohibited both because the electrons that carry the current encounter the boundaries of the cluster and because there are no quantum states readily available at energies just above those of the occupied states, which are the states that must be achieved to allow the electrons to move. However, if a field of alternating electric force is applied with a frequency of alternation so high that the electrons are made to reverse their paths before they encounter the boundaries of the cluster, then the equivalent of conduction will take place. Ordinary 60-cycle (60-hertz) alternating voltage and even alternations at radio-wave frequencies switch direction far too slowly to produce this behaviour in clusters; microwave frequencies are required.

Magnetic properties of clusters, in contrast, appear to be rather similar to those of bulk matter. They are not identical, because clusters contain only small numbers of electrons, which are the particles whose magnetic character makes clusters and bulk matter magnetic. As a result, the differences between magnetic properties of clusters and of bulk matter are more a matter of degree than of kind. Clusters of substances magnetic in the bulk also tend to be magnetic. The larger the cluster, the more nearly will the magnetic character per atom approach that of the bulk. The degree of this magnetic character depends on how strongly the individual electron magnets couple to each other to become aligned in the same direction; the larger the cluster, the stronger is this coupling.

Optical properties

The optical properties of weakly bound clusters are much like those of their component atoms or molecules; the small differences are frequently useful diagnostics of how the cluster is bound and what its structure may be. Optical properties of metal clusters are more like those of the corresponding bulk metals than like those of the constituent atoms. These properties reveal which cluster sizes are unusually stable and therefore correspond to "magic-number" sizes. Optical properties of covalently bound clusters are in most cases—*e.g.*, fullerenes—unlike those of either the component atoms or the bulk but are important clues to the structure and bonding of the cluster.

CHEMICAL PROPERTIES

The chemical properties of clusters are a combination of the properties of bulk and molecular matter. Several kinds of clusters, particularly those of the metallic variety, induce certain molecules to dissociate. For example, hydrogen molecules, H_2, spontaneously break into two hydrogen atoms when they attach themselves to a cluster of iron atoms. Ammonia likewise dissociates when attaching itself to an iron cluster. Similar reactions occur with bulk matter, but the rate at which such gases react with bulk metals depends only on how much gaseous reactant is present and how much surface area the bulk metal presents to the gas. Metal powders react much faster than dense solids with the same total mass because they have much more surface area. Small and medium-size clusters, on the other hand, show different reactivities for every size, although these reactivities do not vary smoothly with size. Furthermore, there are instances, such as reactions of hydrogen with iron, in which two different geometric forms of clusters of a single size have different reaction rates, just as two different molecules with the same elemental composition, called chemical isomers, may have different reaction rates with the same reactant partner. In the case of molecules, this is not surprising, because different isomers typically have quite different structures, physical properties, and reactivities and do not normally transform readily into one another. Isomers of clusters of a specific chemical composition, however, may well transform into one another with moderate ease and with no excessive increase in energy above the amount present when they formed. If the reaction releases energy (*i.e.*, it is exothermic) in sufficient quantity to transform the cluster from solid to liquid, a cluster may melt as it reacts.

Cluster-induced dissociation

Some of the interesting chemistry of clusters is set in motion by light. For example, light of sufficiently short wavelength can dissociate molecules that are captured in the middle of a cluster of nonreactive atoms or molecules. A common question is whether the surrounding molecules or atoms form a cage strong enough to prevent the fragment atoms from flying apart and from leaving the cluster. The answer is that, if there are only a few surrounding atoms or molecules, the fragments escape their initial cage, and, if the energy of the light is high enough, at least one of the fragments escapes. On the other hand, if there are enough nonreacting cage atoms or molecules in the cluster to form at least one complete shell around the molecule that breaks up, the cage usually holds the fragments close together until they eventually recombine.

A related sort of reaction, another example of competition between a particle's attempt to escape from a cluster and some other process, occurs if light is used to detach an excess electron from a negative ion in the middle of an inert cluster. If, for example, light knocks the extra electron off a free, negatively charged bromine molecule, Br_2^-, the

electron of course escapes. If the charged molecule is surrounded by a few inert molecules of carbon dioxide (CO_2), the electron escapes almost as readily. If 10 or 15 CO_2 molecules encase the Br_2^-, the electron does not escape; instead, it loses its energy to the surrounding molecules of CO_2, some of which boil off, and then eventually recombines with the now neutral bromine molecule to re-form the original Br_2^-.

The chemical properties of fullerenes and other network compounds have become a subject of their own, bridging molecular and cluster chemistry. These compounds typically react with a specific number of other atoms or molecules to form new species with definite compositions and structures. Compounds such as K_3C_{60} mentioned previously have the three potassium atoms outside the C_{60} cage, all as singly charged ions, K^+, and the ball of 60 carbon atoms carries three negative charges to make the entire compound electrically neutral. Other compounds of C_{60}, such as that made with the metal lanthanum, contain the metal inside the carbon cage, forming a new kind of substance. It is possible to add or take away hydrogen atoms from C_{60} and its larger relatives, much as hydrogen atoms can be added or removed from some kinds of hydrocarbons; in this way some of the chemistry of this class of clusters is similar to classical organic chemistry.

One of the goals of cluster science is the creation of new kinds of materials. The possible preparation of diamond films is one such application; another example is the proposal to make so-called superatoms that consist of an electron donor atom in the centre of a cluster of electron acceptors; the fullerene clusters containing a metal ion inside the cage seem to be just such a species but with much more open structures than had been previously envisioned. Molecular electronics is another goal; in this technology clusters would be constructed with electrical properties much like those of transistors and could be packed together to make microcircuits far smaller than any now produced. These applications are still theoretical, however, and have not yet been realized.

Clusters do indeed form a bridge between bulk and molecular matter. Their physical and chemical properties are in many instances unique to their finely divided state. Some examples of clusters, such as the network clusters of carbon, are new forms of matter. Nevertheless, such clusters, particularly the small and middle-size ones, not only exhibit behaviours of their own but also provide new insights into the molecular origins of the properties of bulk matter. They may yield other new materials—*e.g.*, possibly far more disordered, amorphous glasslike substances than the glasses now in common use—and at the same time give rise to deeper understanding of why and how glasses form at all. (R.S.Be.)

LOW-TEMPERATURE PHENOMENA

The term low-temperature phenomena refers to the behaviour of matter at temperatures closer to absolute zero (−273.15° C [−459.67° F]) than to room temperature. At such temperatures the thermal, electric, and magnetic properties of many substances undergo great change, and, indeed, the behaviour of matter may seem strange when compared with that at room temperature. Superconductivity and superfluidity can be cited as two such phenomena that occur below certain critical temperatures; in the former, many chemical elements, compounds, and alloys show no resistance whatsoever to the flow of electricity, and, in the latter, liquid helium can flow through tiny holes impervious to any other liquid.

Superconductivity

Superconductivity was discovered in 1911 by the Dutch physicist Heike Kamerlingh Onnes; he was awarded the Nobel Prize for Physics in 1913 for his low-temperature research. Kamerlingh Onnes found that the electrical resistivity of a mercury wire disappears suddenly when it is cooled below a temperature of about 4 K (−269° C); absolute zero is 0 K, the temperature at which all matter loses its disorder. He soon discovered that a superconducting material can be returned to the normal (*i.e.*, nonsuperconducting) state either by passing a sufficiently large current through it or by applying a sufficiently strong magnetic field to it.

For many years it was believed that, except for the fact that they had no electrical resistance (*i.e.*, that they had infinite electrical conductivity), superconductors had the same properties as normal materials. This belief was shattered in 1933 by the discovery that a superconductor is highly diamagnetic; that is, it is strongly repelled by and tends to expel a magnetic field. This phenomenon, which is very strong in superconductors, is called the Meissner effect for one of the two men who discovered it. Its discovery made it possible to formulate, in 1934, a theory of the electromagnetic properties of superconductors that predicted the existence of an electromagnetic penetration depth (see below *The Meissner effect*), which was first confirmed experimentally in 1939. In 1950 it was clearly shown for the first time that a theory of superconductivity must take into account the fact that free electrons in a crystal are influenced by the vibrations of atoms that define the crystal structure, called the lattice vibrations. In 1953, in an analysis of the thermal conductivity of superconductors, it was recognized that the distribution of energies of the free electrons in a superconductor is not uniform but has a separation called the energy gap.

The theories referred to thus far served to show some of the interrelationships between observed phenomena but did not explain them as consequences of the fundamental laws of physics. For almost 50 years after Kamerlingh Onnes' discovery, theorists were unable to develop a fundamental theory of superconductivity. Finally, in 1957 such a theory was presented by the physicists John Bardeen, Leon N. Cooper, and John Robert Schrieffer of the United States; it won for them the Nobel Prize for Physics in 1972. It is now called the BCS theory in their honour, and most later theoretical work is based on it. The BCS theory also provided a foundation for an earlier model that had been introduced by the Russian physicists Lev Davidovich Landau and Vitaly Lazarevich Ginzburg (1950). This model has been useful in understanding electromagnetic properties, including the fact that any internal magnetic flux in superconductors exists only in discrete amounts (instead of in a continuous spectrum of values), an effect called the quantization of magnetic flux. This flux quantization, which had been predicted from quantum mechanical principles, was first observed experimentally in 1961. The BCS theory

In 1962 the British physicist Brian D. Josephson predicted that two superconducting objects placed in electric contact would display certain remarkable electromagnetic properties. These properties have since been observed in a wide variety of experiments, demonstrating quantum mechanical effects on a macroscopic scale.

The theory of superconductivity has been tested in a wide range of experiments, involving, for example, ultrasonic absorption studies, nuclear-spin phenomena, low-frequency infrared absorption, and electron-tunneling experiments (see below *Energy gaps*). The results of these measurements have brought understanding to many of the detailed properties of various superconductors.

THERMAL PROPERTIES OF SUPERCONDUCTORS

Superconductivity is a startling departure from the properties of normal (*i.e.*, nonsuperconducting) conductors of electricity. In materials that are electric conductors, some of the electrons are not bound to individual atoms but are free to move through the material; their motion constitutes an electric current. In normal conductors these so-called conduction electrons are scattered by impurities, dislocations, grain boundaries, and lattice vibrations (phonons). In a superconductor, however, there is an ordering among

the conduction electrons that prevents this scattering. Consequently, electric current can flow with no resistance at all. The ordering of the electrons, called Cooper pairing, involves the momenta of the electrons rather than their positions. The energy per electron that is associated with this ordering is extremely small, typically about one thousandth of the amount by which the energy per electron changes when a chemical reaction takes place. One reason that superconductivity remained unexplained for so long is the smallness of the energy changes that accompany the transition between normal and superconducting states. In fact, many incorrect theories of superconductivity were advanced before the BCS theory was proposed. For additional details on electric conduction in metals and the effects of temperature and other influences, see the article ELECTRICITY AND MAGNETISM.

Superconducting materials

Hundreds of materials are known to become superconducting at low temperatures. Twenty-seven of the chemical elements, all of them metals, are superconductors in their usual crystallographic forms at low temperatures and low (atmospheric) pressure. Among these are commonly known metals such as aluminum, tin, lead, and mercury and less common ones such as rhenium, lanthanum, and protactinium. In addition, 11 chemical elements that are metals, semimetals, or semiconductors are superconductors at low temperatures and high pressures. Among these are uranium, cerium, silicon, and selenium. Bismuth and five other elements, though not superconducting in their usual crystallographic form, can be made superconducting by preparing them in a highly disordered form, which is stable at extremely low temperatures. Superconductivity is not exhibited by any of the magnetic elements chromium, manganese, iron, cobalt, or nickel.

Most of the known superconductors are alloys or compounds. It is possible for a compound to be superconducting even if the chemical elements constituting it are not; examples are disilver fluoride (Ag_2F) and a compound of carbon and potassium (C_8K). Some semiconducting compounds, such as tin telluride (SnTe), become superconducting if they are properly doped with impurities.

Since 1986 some compounds containing copper and oxygen (called cuprates) have been found to have extraordinarily high transition temperatures, denoted T_c. This is the temperature below which a substance is superconducting. The properties of these high-T_c compounds are different in some respects from those of the types of superconductors known prior to 1986, which will be referred to as classic superconductors in this discussion. For the most part, the high-T_c superconductors are treated explicitly toward the end of this section. In the discussion that immediately follows, the properties possessed by both kinds of superconductors will be described, with attention paid to specific differences for the high-T_c materials. A further classification problem is presented by the superconducting compounds of carbon (sometimes doped with other atoms) in which the carbon atoms are on the surface of a cluster with a spherical or spheroidal crystallographic structure. These compounds, discovered in the 1980s, are called fullerenes (if only carbon is present) or fullerides (if doped). They have superconducting transition temperatures higher than those of the classic superconductors. It is not yet known whether these compounds are fundamentally similar to the cuprate high-temperature superconductors.

Transition temperatures. The vast majority of the known superconductors have transition temperatures that lie between 1 K and 10 K. Of the chemical elements, tungsten has the lowest transition temperature, 0.015 K, and niobium the highest, 9.2 K. The transition temperatures of some of the commonly known superconducting elements are indicated in Table 9.

Table 9: Transition Temperatures and Low-Temperature Values of Critical Magnetic Fields of Some Superconducting Elements

	Tc (K)	*Ho* (oersted)
Zinc	0.88	53
Aluminum	1.20	99
Indium	3.41	282
Tin	3.72	306
Mercury	4.15	411
Lead	7.19	803

The transition temperature is usually very sensitive to the presence of magnetic impurities. A few parts per million of manganese in zinc, for example, lowers the transition temperature considerably.

Specific heat and thermal conductivity. The thermal properties of a superconductor can be compared with those of the same material at the same temperature in the normal state. (The material can be forced into the normal state at low temperature by a large enough magnetic field.)

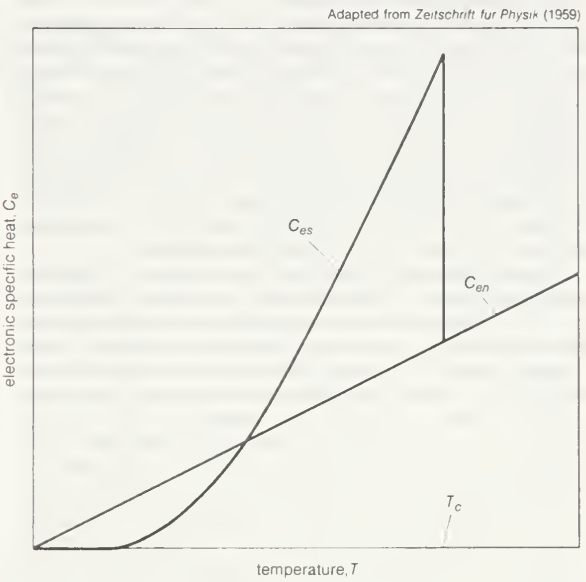

Figure 49: Specific heat in the normal (C_{en}) and superconducting (C_{es}) states of a classic superconductor as a function of absolute temperature. The two functions are identical at the transition temperature (T_c) and above T_c.

When a small amount of heat is put into a system, some of the energy is used to increase the lattice vibrations (an amount that is the same for a system in the normal and in the superconducting state), and the remainder is used to increase the energy of the conduction electrons. The electronic specific heat (C_e) of the electrons is defined as the ratio of that portion of the heat used by the electrons to the rise in temperature of the system. Figure 49 shows how the specific heat of the electrons in a superconductor varies with the absolute temperature (T) in the normal and in the superconducting state. It is evident from the figure that the electronic specific heat in the superconducting state (designated C_{es}) is smaller than in the normal state (designated C_{en}) at low enough temperatures but that C_{es} becomes larger than C_{en} as the transition temperature T_c is approached, at which point it drops abruptly to C_{en} for the classic superconductors, although the curve has a cusp shape near T_c for the high-T_c superconductors. Precise measurements have indicated that, at temperatures considerably below the transition temperature, the logarithm of the electronic specific heat is inversely proportional to the temperature. This temperature dependence, together with the principles of statistical mechanics, strongly suggests that there is a gap in the distribution of energy levels available to the electrons in a superconductor, so that a minimum energy is required for the excitation of each electron from a state below the gap to a state above the gap. Some of the high-T_c superconductors provide an additional contribution to the specific heat, which is proportional to the temperature. This behaviour indicates that there are electronic states lying at low energy; additional evidence of such states is obtained from optical properties and tunneling measurements.

Temperature dependence of electronic specific heat

The heat flow per unit area of a sample equals the product of the thermal conductivity (K) and the temperature gradient ∇T: $J_Q = -K \nabla T$, the minus sign indicating that heat always flows from a warmer to a colder region of a substance.

The thermal conductivity in the normal state (K_n) approaches the thermal conductivity in the superconducting state (K_s) as the temperature (T) approaches the transition temperature (T_c) for all materials, whether they are pure or impure. This suggests that the energy gap (Δ) for each electron approaches zero as the temperature (T) approaches the transition temperature (T_c). This would also account for the fact that the electronic specific heat in the superconducting state (C_{es}) is higher than in the normal state (C_{en}) near the transition temperature: as the temperature is raised toward the transition temperature (T_c), the energy gap in the superconducting state decreases, the number of thermally excited electrons increases, and this requires the absorption of heat.

Energy gaps. As stated above, the thermal properties of superconductors indicate that there is a gap in the distribution of energy levels available to the electrons, and so a finite amount of energy, designated as delta (Δ), must be supplied to an electron to excite it. This energy is maximum (designated Δ_0) at absolute zero and changes little with increase of temperature until the transition temperature is approached, where Δ decreases to zero, its value in the normal state. The BCS theory predicts an energy gap with just this type of temperature dependence.

Cooper electron pairs

According to the BCS theory, there is a type of electron pairing (electrons of opposite spin acting in unison) in the superconductor that is important in interpreting many superconducting phenomena. The electron pairs, called Cooper pairs, are broken up as the superconductor is heated. Each time a pair is broken, an amount of energy that is at least as much as the energy gap (Δ) must be supplied to each of the two electrons in the pair, so an energy at least twice as great (2Δ) must be supplied to the superconductor. The value of twice the energy gap at 0 K (which is $2\Delta_0$) might be assumed to be higher when the transition temperature of the superconductor is higher. In fact, the BCS theory predicts a relation of this type—namely, that the energy supplied to the superconductor at absolute zero would be $2\Delta_0 = 3.53\ kT_c$, where k is Boltzmann's constant (1.38×10^{-23} joule per kelvin). In the high-T_c cuprate compounds, values of $2\Delta_0$ range from approximately three to eight multiplied by kT_c.

The energy gap (Δ) can be measured most precisely in a tunneling experiment (a process in quantum mechanics that allows an electron to escape from a metal without acquiring the energy required along the way according to the laws of classical physics). In this experiment, a thin insulating junction is prepared between a superconductor and another metal, assumed here to be in the normal state. In this situation, electrons can quantum mechanically tunnel from the normal metal to the superconductor if they have sufficient energy. This energy can be supplied by applying a negative voltage (V) to the normal metal, with respect to the voltage of the superconductor.

Tunneling will occur if eV—the product of the electron charge, e (-1.60×10^{-19} coulomb), and the voltage—is at least as large as the energy gap Δ. The current flowing between the two sides of the junction is small up to a voltage equal to $V = \Delta/e$, but then it rises sharply. This provides an experimental determination of the energy gap (Δ). In describing this experiment it is assumed here that the tunneling electrons must get their energy from the applied voltage rather than from thermal excitation.

MAGNETIC AND ELECTROMAGNETIC PROPERTIES OF SUPERCONDUCTORS

Critical field. One of the ways in which a superconductor can be forced into the normal state is by applying a magnetic field. The weakest magnetic field that will cause this transition is called the critical field (H_c) if the sample is in the form of a long, thin cylinder or ellipsoid and the field is oriented parallel to the long axis of the sample. (In other configurations the sample goes from the superconducting state into an intermediate state, in which some regions are normal and others are superconducting, and finally into the normal state.) The critical field increases with decreasing temperature. For the superconducting elements, its values (H_0) at absolute zero range from 1.1 oersted for tungsten to 830 oersteds for tantalum. Values of H_0 are listed in Table 9 for some common superconducting elements.

These remarks about the critical field apply to ordinary (so-called type I) superconductors. In the following section the behaviour of other (type II) superconductors is examined.

The Meissner effect. As was stated above, a type I superconductor in the form of a long, thin cylinder or ellipsoid remains superconducting at a fixed temperature as an axially oriented magnetic field is applied, provided the applied field does not exceed a critical value (H_c). Under these conditions, superconductors exclude the magnetic field from their interior, as could be predicted from the laws of electromagnetism and the fact that the superconductor has no electric resistance. A more astonishing effect occurs if the magnetic field is applied in the same way to the same type of sample at a temperature above the transition temperature and is then held at a fixed value while the sample is cooled. It is found that the sample expels the magnetic flux as it becomes superconducting. This is called the Meissner effect. Complete expulsion of the magnetic flux (a complete Meissner effect) occurs in this way for certain superconductors, called type I superconductors, but only for samples that have the described geometry. For samples of other shapes, including hollow structures, some of the magnetic flux can be trapped, producing an incomplete or partial Meissner effect.

Behaviour of type II superconductors

Type II superconductors have a different magnetic behaviour. Examples of materials of this type are niobium and vanadium (the only type II superconductors among the chemical elements) and some alloys and compounds, including the high-T_c compounds. As a sample of this type, in the form of a long, thin cylinder or ellipsoid, is exposed to a decreasing magnetic field that is axially oriented with the sample, the increase of magnetization, instead of occurring suddenly at the critical field (H_c), sets in gradually. Beginning at the upper critical field (H_{c2}), it is completed at a lower critical field (H_{c1}; see Figure 50). If the sample is of some other shape, is hollow, or is inhomogeneous or strained, some magnetic flux remains trapped, and some magnetization of the sample remains after the applied field is completely removed. Known values of the upper critical field extend up to 6×10^5 oersteds, the value for the compound of lead, molybdenum, and sulfur with formula $PbMo_6S_8$.

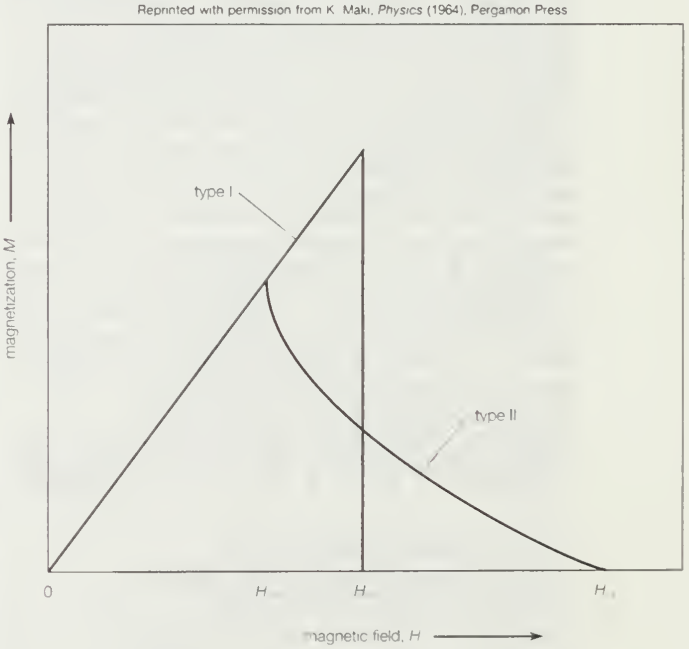

Figure 50: Magnetization as a function of magnetic field for a type I superconductor and a type II superconductor. For type I, magnetic flux is expelled, producing a magnetization (M) that increases with magnetic field (H) until a critical field (H_c) is reached, at which it falls to zero as with a normal conductor. A type II superconductor has two critical magnetic fields (H_{c1} and H_{c2}); below H_{c1} type II behaves as type I, and above H_{c2} it becomes normal.

The expulsion of magnetic flux by type I superconductors in fields below the critical field (H_c) or by type II superconductors in fields below H_{c1} is never quite as complete as has been stated in this simplified presentation, because the field always penetrates into a sample for a small distance, known as the electromagnetic penetration depth. Values of the penetration depth for the superconducting elements at low temperature lie in the range from about 390 to 1300 angstroms. As the temperature approaches the critical temperature, the penetration depth becomes extremely large.

Electromagnetic penetration depth

High-frequency electromagnetic properties. The foregoing descriptions have pertained to the behaviour of superconductors in the absence of electromagnetic fields or in the presence of steady or slowly varying fields; the properties of superconductors in the presence of high-frequency electromagnetic fields, however, have also been studied.

The energy gap in a superconductor has a direct effect on the absorption of electromagnetic radiation. At low temperatures, at which a negligible fraction of the electrons are thermally excited to states above the gap, the superconductor can absorb energy only in a quantized amount that is at least twice the gap energy (at absolute zero, $2\Delta_0$). In the absorption process, a photon (a quantum of electromagnetic energy) is absorbed, and a Cooper pair is broken; both electrons in the pair become excited. The photon's energy (E) is related to its frequency (ν) by the Planck relation, $E = h\nu$, in which h is Planck's constant (6.63×10^{-34} joule second). Hence the superconductor can absorb electromagnetic energy only for frequencies at least as large as $2\Delta_0/h$.

Magnetic-flux quantization. The laws of quantum mechanics dictate that electrons have wave properties and that the properties of an electron can be summed up in what is called a wave function. If several wave functions are in phase (*i.e.*, act in unison), they are said to be coherent. The theory of superconductivity indicates that there is a single, coherent, quantum mechanical wave function that determines the behaviour of all the superconducting electrons. As a consequence, a direct relationship can be shown to exist between the velocity of these electrons and the magnetic flux (Φ) enclosed within any closed path inside the superconductor. Indeed, inasmuch as the magnetic flux arises because of the motion of the electrons, the magnetic flux can be shown to be quantized; *i.e.*, the intensity of this trapped flux can change only by units of Planck's constant divided by twice the electron charge.

When a magnetic field enters a type II superconductor (in an applied field between the lower and upper critical fields, H_{c1} and H_{c2}), it does so in the form of quantized fluxoids, each carrying one quantum of flux. These fluxoids tend to arrange themselves in regular patterns that have been detected by electron microscopy and by neutron diffraction. If a large enough current is passed through the superconductor, the fluxoids move. This motion leads to energy dissipation that can heat the superconductor and drive it into the normal state. The maximum current per unit area that a superconductor can carry without being forced into the normal state is called the critical current density (J_c). In making wire for superconducting high-field magnets, manufacturers try to fix the positions of the fluxoids by making the wire inhomogeneous in composition.

Fluxoids

Josephson currents. If two superconductors are separated by an insulating film that forms a low-resistance junction between them, it is found that Cooper pairs can tunnel from one side of the junction to the other. (This process occurs in addition to the single-particle tunneling already described.) Thus, a flow of electrons, called the Josephson current, is generated and is intimately related to the phases of the coherent quantum mechanical wave function for all the superconducting electrons on the two sides of the junction. It was predicted that several novel phenomena should be observable, and experiments have demonstrated them. These are collectively called the Josephson effect or effects.

The first of these phenomena is the passage of current through the junction in the absence of a voltage across the junction. The maximum current that can flow at zero voltage depends on the magnetic flux (Φ) passing through the junction as a result of the magnetic field generated by currents in the junction and elsewhere. The dependence of the maximum zero-voltage current on the magnetic field applied to a junction between two superconductors is shown in Figure 51.

A second type of Josephson effect is an oscillating current resulting from a relation between the voltage across the junction and the frequency (ν) of the currents associated with Cooper pairs passing through the junction. The frequency (ν) of this Josephson current is given by $\nu = 2eV/h$, where e is the charge of the electron. Thus, the frequency increases by 4.84×10^{14} hertz (cycles per second) for each additional volt applied to the junction. This effect can be demonstrated in various ways. The voltage can be established with a source of direct-current (DC) power, for instance, and the oscillating current can be detected by the electromagnetic radiation of frequency (ν) that it generates. Another method is to expose the junction to radiation of another frequency (ν') generated externally. It is found that a graph of the DC current versus voltage has current steps at values of the voltage corresponding to Josephson frequencies that are integral multiples (n) of the external frequency ($\nu = n\nu'$); that is, $V = nh\nu'/2e$. The observation of current steps of this type has made it possible to measure h/e with far greater precision than by any other method and has therefore contributed to a knowledge of the fundamental constants of nature.

Oscillating currents

The Josephson effect has been used in the invention of novel devices for extremely high-sensitivity measurements of currents, voltages, and magnetic fields.

Figure 51: Maximum zero-voltage (Josephson) current passing through a junction by Cooper-pair tunneling as a function of magnetic field.

HIGHER-TEMPERATURE SUPERCONDUCTIVITY

Ever since Kamerlingh Onnes discovered that mercury becomes superconducting at temperatures less than 4 K, scientists have been searching for superconducting materials with higher transition temperatures. Until 1986 a compound of niobium and germanium (Nb_3Ge) had the highest known transition temperature, 23 K, less than a 20-degree increase in 75 years. Most researchers expected that the next increase in transition temperature would be found in a similar metallic alloy and that the rise would be only one or two degrees. In 1986, however, the Swiss physicist Karl Alex Müller and his West German associate, Johannes Georg Bednorz, discovered, after a three-year search among metal oxides, a material that had an unprecedentedly high transition temperature of about 30 K. They were awarded the Nobel Prize for Physics in 1987, and their discovery immediately stimulated groups of investigators in China, Japan, and the United States to produce superconducting oxides with even higher transition temperatures.

These high-temperature superconductors are ceramics. They contain lanthanum, yttrium, or another of the rare-earth elements or bismuth or thallium; usually barium or strontium (both alkaline-earth elements); copper; and oxygen. Other atomic species can sometimes be introduced by chemical substitution while retaining the high-T_c properties. The superconducting transition temperatures of some of the high-T_c materials are listed in Table 10. The value 134 K is the highest known T_c value. The compounds given in the table are members of the major families of high-T_c superconductors. Within each family, only the subscripts (*i.e.*, stoichiometry) vary from one compound to another. The compounds listed have the highest observed superconducting transition temperature in their respective families. Samples in the families containing bismuth or thallium always exhibit a great deal of atomic disorder, with atoms in the "wrong" crystallographic sites and with impurity phases. It is possible that such disorder is required to make these compounds thermodynamically stable.

Table 10: Transition Temperatures of Some High-T_c Superconductors

compound	T_c (K)
$Nd_{1.85}Ce_{0.15}CuO_4$	24
$La_{1.85}Sr_{0.15}CuO_4$	40
$YBa_2Cu_3O_7$	92
$Bi_2Sr_2Ca_2Cu_3O_{10}$	110
$Tl_2Ba_2Ca_2Cu_3O_{10}$	127
$Hg_2Ba_2Ca_2Cu_3O_8$	134

The compounds have crystal structures containing planes of Cu and O atoms, and some also have chains of Cu and O atoms. The roles played by these planes and chains have come under intense investigation. Varying the oxygen content or the heat treatment of the materials dramatically changes their transition temperatures, critical magnetic fields, and other properties. Single crystals of the high-temperature superconductors are very anisotropic—*i.e.*, their properties associated with a direction, such as the critical fields or the critical current density, are highly dependent on the angle between that direction and the rows of atoms in the crystal.

If the number of superconducting electrons per unit volume is locally disturbed by an applied force (typically electric or magnetic), this disturbance propagates for a certain distance in the material; the distance is called the superconducting coherence length (or Ginzburg-Landau coherence length), ξ. If a material has a superconducting region and a normal region, many of the superconducting properties disappear gradually—over a distance ξ—upon traveling from the former to the latter region. In the pure (*i.e.*, undoped) classic superconductors ξ is on the order of a few thousand angstroms, but in the high-T_c superconductors it is on the order of 1 to 10 angstroms. The small size of ξ affects the thermodynamic and electromagnetic properties of the high-T_c superconductors. For example, it is responsible for the cusp shape of the specific heat curve near T_c that was mentioned above. It is also responsible for the ability of the high-T_c superconductors to remain superconducting in extraordinarily large fields—on the order of 1,000,000 gauss (100 teslas)—at low temperatures.

The high-T_c superconductors are type II superconductors. They exhibit zero resistance, strong diamagnetism, the Meissner effect, magnetic flux quantization, the Josephson effects, an electromagnetic penetration depth, an energy gap for the superconducting electrons, and the characteristic temperature dependences of the specific heat and the thermal conductivity that are described above. Therefore, it is clear that the conduction electrons in these materials form the Cooper pairs used to explain superconductivity in the BCS theory. Thus, the central conclusions of the BCS theory are demonstrated. Indeed, that theory guided Bednorz and Müller in their search for high-temperature superconductors. It is not known, however, why the transition temperatures of these oxides are so high. It was generally believed that the members of a Cooper pair are bound together because of interactions between the electrons and the lattice vibrations (phonons), but it is unlikely that these interactions are strong enough to explain transition temperatures as high as 90 K. Most experts believe that interactions among the electrons generate high-temperature superconductivity. The details of this interaction are difficult to treat theoretically because the motions of the electrons are strongly correlated with each other and because magnetic phenomena play an important part in determining the microscopic properties of these materials. These strong correlations and magnetic properties may be responsible for unusual temperature dependencies of the electric resistivity ρ and Hall coefficient R_H in the normal state (*i.e.*, above T_c). (For a discussion of the Hall effect, see ELECTRICITY AND MAGNETISM: *Magnetism: Magnetic forces.*) It is observed that at temperatures above T_c the electric resistivity, although higher for superconductors than for typical metals in the normal state, is roughly proportional to the temperature T, an unusually weak temperature dependence. Measurements of R_H show it to be significantly temperature-dependent in the normal state (sometimes proportional to $1/T$) rather than being roughly independent of T, which is the case for ordinary materials.

Applications of high-temperature superconductors

Films of the new materials can carry currents in the superconducting state that are large enough to be of importance in making many devices. Possible applications of the high-temperature superconductors in thin-film or bulk form include the construction of computer parts (logic devices, memory elements, switches, and interconnects), oscillators, amplifiers, particle accelerators, highly sensitive devices for measuring magnetic fields, voltages, or currents, magnets for medical magnetic-imaging devices, magnetic energy-storage systems, levitated passenger trains for high-speed travel, motors, generators, transformers, and transmission lines. The principal advantages of these superconducting devices would be their low power dissipation, high operating speed, and extreme sensitivity.

Equipment made with the high-temperature superconductors would also be more economical to operate because such materials can be cooled with inexpensive liquid nitrogen (boiling point, 77 K) rather than with costly liquid helium (boiling point, 4.2 K). The ceramics have problems, however, which must be overcome before useful devices can be made from them. These problems include brittleness, instabilities of the materials in some chemical environments, and a tendency for impurities to segregate at surfaces and grain boundaries, where they interfere with the flow of high currents in the superconducting state. (D.M.Gi.)

Superfluidity

The phenomenon of superfluidity has so far been directly observed only in the liquid forms of the two stable isotopes of helium, ^{4}He and ^{3}He, both of which remain liquid under their own vapour pressure down to the lowest temperatures reached thus far. In the case of the more abundant isotope, ^{4}He, superfluidity occurs at temperatures below the so-called lambda transition, which is 2.17 K. It is so named because the graph of the specific heat versus the temperature near this point has a shape resembling the Greek letter lambda. For ^{3}He, superfluidity is observed only at temperatures far closer to absolute zero, below 3×10^{-3} K. It is believed that superfluidity may occur in some other systems, such as neutron stars, but the evidence in these cases is much less direct.

Superfluid phenomena

The most spectacular signature of the transition of liquid ^{4}He into the superfluid phase is the sudden onset of the ability to flow without apparent friction through capillaries so small that any ordinary liquid (including ^{4}He itself above the lambda transition) would be clamped by its viscosity; thus, a vessel that was "helium-tight" in the so-called normal phase (*i.e.*, above the lambda temperature) might suddenly spring leaks below it. Related phenomena observed in the superfluid phase include the ability to sustain persistent currents in a ring-shaped container; the phenomenon of film creep, in which the liquid flows without apparent friction up and over the side of a bucket containing it; and a thermal conductivity that is millions of times its value in the normal phase and greater than that of the best metallic conductors. Another property is

less spectacular but is extremely significant for an understanding of the superfluid phase: if the liquid is cooled through the lambda transition in a bucket that is slowly rotating, then, as the temperature decreases toward absolute zero, the liquid appears gradually to come to rest with respect to the laboratory even though the bucket continues to rotate. This nonrotation effect is completely reversible; the apparent velocity of rotation depends only on the temperature and not on the history of the system. Most of these phenomena also have been observed in the superfluid phase of liquid ^{3}He, though in somewhat less spectacular form.

It is thought that there is a close connection between the phenomena of superfluidity and superconductivity; indeed, from a phenomenological point of view superconductivity is simply superfluidity occurring in an electrically charged system. Thus, the frictionless flow of superfluid ^{4}He through narrow capillaries parallels the frictionless carrying of electric current by the electrons in a superconductor, and the ability of helium to sustain circulating mass currents in a ring-shaped container is closely analogous to the persistence of electric currents in a superconducting ring. Less obviously, it turns out that the nonrotation effect is the exact analogue of the Meissner effect in superconductors (see above *Superconductivity*). Many other characteristic features of superconductivity, such as the existence of vortices and the Josephson effect, have been observed in the superfluid phases of both ^{4}He and ^{3}He.

The accepted theoretical understanding of superfluidity (or superconductivity) is based on the idea that an extremely large number of atoms (or electrons) show identical, and moreover essentially quantum mechanical, behaviour; that is to say, the system is described by a single, coherent, quantum mechanical wave function. A single electron in an atom cannot rotate around the nucleus in any arbitrary orbit; rather, quantum mechanics requires that it rotate in such a way that its angular momentum is quantized so as to be a multiple (including zero) of $h/2\pi$, where h is Planck's constant. This is the origin of, for example, the phenomenon of atomic diamagnetism. Similarly, a single atom (or molecule) placed in a ring-shaped container is allowed by quantum mechanics to travel around the ring with only certain definite velocities, including zero. In an ordinary liquid such as water, the thermal disorder ensures that the atoms (or molecules) are distributed over the different (quantized) states available to them in such a way that the average velocity is not quantized; thus, when the container rotates and the liquid is given sufficient time to come into equilibrium, it rotates along with the container in accordance with everyday experience.

In a superfluid system the situation is quite different. The simpler case is that of ^{4}He, a liquid consisting of atoms that have total spin angular momentum equal to zero and whose distribution between their possible states is therefore believed to be governed by a principle known as Bose statistics. A gas of such atoms without interactions between them would undergo, at some temperature T_0, a phenomenon known as Bose condensation; below T_0 a finite fraction of all the atoms occupy a single state, normally that of lowest energy, and this fraction increases toward one as the temperature falls toward absolute zero. These atoms are said to be condensed. It is widely believed that a similar phenomenon should also occur for a liquid such as ^{4}He, in which the interaction between atoms is quite important, and that the lambda transition of ^{4}He is just the onset of Bose condensation. (The reason that this phenomenon is not seen in other systems of spin-zero atoms such as neon-22 is simply that, as the temperature is lowered, freezing occurs first.) If this is so, then, for temperatures below the lambda transition, a finite fraction of all the atoms must decide cooperatively which one of the possible quantized states they will all occupy. In particular, if the container is rotating at a sufficiently slow speed, these condensed atoms will occupy the nonrotating state—*i.e.*, they will be at rest with respect to the laboratory—while the rest will behave normally and will distribute themselves in such a way that on average they rotate with the container. As a result, as the temperature is lowered and the fraction of condensed atoms increases, the liquid will appear gradually to come to rest with respect to the laboratory (or, more accurately, to the fixed stars). Similarly, when the liquid is flowing through a small capillary, the condensed atoms cannot be scattered by the walls one at a time since they are forced by Bose statistics to occupy the same state. They must be scattered, if at all, simultaneously. Since this process is extremely improbable, the liquid, or more precisely the condensed fraction of it, flows without any apparent friction. The other characteristic manifestations of superfluidity can be explained along similar lines.

The idea of Bose condensation is not directly applicable to liquid ^{3}He, because ^{3}He atoms have spin angular momentum equal to 1/2 (in units of $h/2\pi$) and their distribution among states is therefore believed to be governed by a different principle, known as Fermi statistics. It is believed, however, that in the superfluid phase of ^{3}He the atoms, like the electrons in a superconductor (see above *Superconductivity*), pair off to form Cooper pairs—a sort of quasimolecular complex—which have integral spin and therefore effectively obey Bose rather than Fermi statistics. In particular, as soon as the Cooper pairs are formed, they undergo a sort of Bose condensation, and subsequently the arguments given above for ^{4}He apply equally to them. As in the case of the electrons in superconductors, a finite energy, the so-called energy gap Δ, is necessary to break up the pairs (or at least most of them), and as a result the thermodynamics of superfluid ^{3}He is quite similar to that of superconductors. There is one important difference between the two cases. Whereas in a classic superconductor the electrons pair off with opposite spins and zero total angular momentum, making the internal structure of the Cooper pairs rather featureless, in ^{3}He the atoms pair with parallel spins and nonzero total angular momentum, so that the internal structure of the pairs is much richer and more interesting. One manifestation of this is that there are three superfluid phases of liquid ^{3}He, called A, B, and A_1, which are distinguished by the different internal structures of the Cooper pairs. The B phase is in most respects similar to a classic superconductor, whereas the A (and A_1) phase is strongly anisotropic in its properties and has an energy gap that actually vanishes for some directions of motion. As a result, some of the superfluid properties of the A and A_1 phases are markedly different from those of ^{4}He or ^{3}He-B and are indeed unique among known physical systems. (A.J.L.)

HIGH-PRESSURE PHENOMENA

Matter undergoes significant changes in physical, chemical, and structural characteristics when subjected to high pressure. Pressure thus serves as a versatile tool in materials research, and it is especially important in the investigation of the rocks and minerals that form the deep interior of the Earth and other planets. Pressure, defined as a force applied to an area, is a thermochemical variable that induces physical and chemical changes comparable to the more familiar effects of temperature. Liquid water, for example, transforms to solid ice when cooled to temperatures below 0° C (32° F), but ice can also be produced at room temperature by compressing water to pressures roughly 10,000 times above atmospheric pressure. Similarly, water converts to its gaseous form at high temperature or at low pressure.

In spite of the superficial similarity between temperature and pressure, these two variables are fundamentally different in the ways they affect a material's internal energy. Temperature variations reflect changes in the kinetic energy and thus in the entropy of vibrating atoms. Increased pressure, on the other hand, alters the electron interaction energy of atomic bonds by forcing atoms closer together in

a smaller volume. Pressure thus serves as a powerful probe of atomic interactions and chemical bonding. Furthermore, pressure is an important tool for synthesizing dense structures, including superhard materials, novel solidified gases and liquids, and mineral-like phases suspected to occur deep within the Earth and other planets.

Units of pressure

Numerous units for measuring pressure have been introduced and, at times, are confused in the literature. The atmosphere (atm; approximately 1.034 kilograms per square centimetre [14.7 pounds per square inch], equivalent to the weight of about 760 millimetres [30 inches] of mercury) and the bar (equivalent to one kilogram per square centimetre) are often cited. Coincidently, these units are almost identical (1 bar = 0.987 atm). The pascal, defined as one newton per square metre (1 Pa = 0.00001 bar), is the official SI (Système International d'Unités) unit of pressure. Nevertheless, the pascal has not gained universal acceptance among high-pressure researchers, perhaps because of the awkward necessity of using the gigapascal (1 GPa = 10,000 bars) and terapascal (1 TPa = 10,000,000 bars) in describing high-pressure results.

In everyday experience, greater-than-ambient pressures are encountered in, for example, pressure cookers (about 1.5 atm), pneumatic automobile and truck tires (usually 2 to 3 atm), and steam systems (up to 20 atm). In the context of materials research, however, "high pressure" usually refers to pressures in the range of thousands to millions of atmospheres.

Studies of matter under high pressure are especially important in a planetary context. Objects in the deepest trench of the Pacific Ocean are subjected to about 0.1 GPa (roughly 1,000 atm), equivalent to the pressure beneath a three-kilometre column of rock. The pressure at the centre of the Earth exceeds 300 GPa, and pressures inside the largest planets—Saturn and Jupiter—are estimated to be roughly 2 and 10 TPa, respectively. At the upper extreme, pressures inside stars may exceed 1,000,000,000 TPa.

Producing high pressure

Scientists study materials at high pressure by confining samples in specially designed machines that apply a force to the sample area. Prior to 1900 these studies were conducted in rather crude iron or steel cylinders, usually with relatively inefficient screw seals. Maximum laboratory pressures were limited to about 0.3 GPa, and explosions of the cylinders were a common and sometimes injurious occurrence. Dramatic improvements in high-pressure apparatuses and measuring techniques were introduced by the American physicist Percy Williams Bridgman of Harvard University in Cambridge, Mass. In 1905 Bridgman discovered a method of packing pressurized samples, including gases and liquids, in such a way that the sealing gasket always experienced a higher pressure than the sample under study, thereby confining the sample and reducing the risk of experimental failure. Bridgman not only routinely attained pressures above 30,000 atm, but he also was able to study fluids and other difficult samples.

LARGE-VOLUME APPARATUSES

Sustained high pressures and temperatures are now commonly produced in massive presses that focus large forces (up to thousands of tons) through two or more strong anvils to compress a sample. The simplest of these devices, introduced by Bridgman in the 1930s, employs two tapered anvils that squeeze the sample like a vise (see Figure 52). Although capable of very high pressures—in excess of 50 GPa in designs with sufficient lateral anvil support—the axial force of the squeezer tends to deform samples into extremely flattened, highly strained disks.

Simple anvil devices

The piston-in-cylinder design, in use for more than a century, incorporates a strong metal or carbide piston that is rammed into a sample-confining cylinder. In principle, the piston can be quite long, so a piston-cylinder design can accommodate a much larger volume of sample than the squeezer, depending on the dimensions of the sample-holding cylinder. These devices are rarely used at pressures above about 10 GPa owing to the likelihood of lateral failure (namely, explosive bursting) of the metal cylinder.

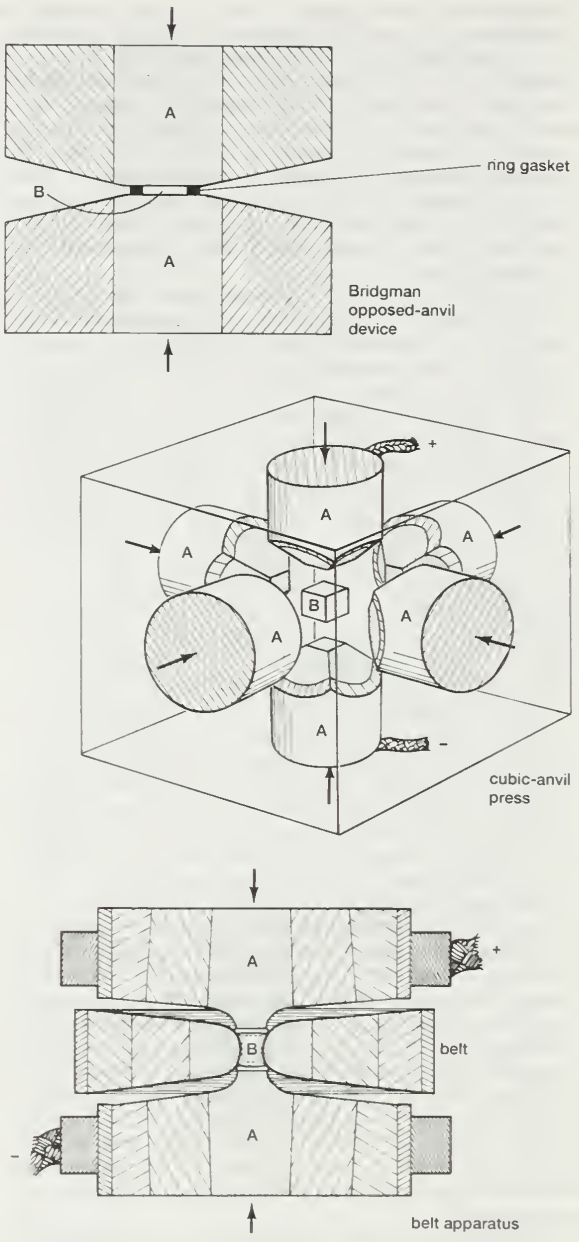

Figure 52: *High-pressure apparatuses.*
In each device, (A) anvils of carbide (stippled) and steel compress (B) a sample. Electric leads (+ and −) provide heating capability.

Adapted from A.A. Giardini and J.E. Tydings, "Diamond Synthesis: Observations on the Mechanism of Formation," *The American Mineralogist*, vol. 47, Nov.–Dec. 1962, pp. 1393–1412, fig. 1 (a & e), copyright by the Mineralogical Society of America

The belt apparatus, invented in 1954 by the scientist Tracy Hall of the General Electric Company for use in the company's diamond-making program, incorporates features of both opposed-anvil and piston-cylinder designs (see Figure 52). Two highly tapered pistonlike anvils compress a sample that is confined in a torus, much like a cylinder open at both ends. Hundreds of belt-type devices are in use worldwide in diamond synthesis.

Many high-pressure researchers now employ split-sphere or multianvil devices, which compress a sample uniformly from all sides. Versions with six anvils that press against the six faces of a cube-shaped sample (see Figure 52) or with eight anvils that compress an octahedral sample are in widespread use. Unlike the simple squeezer, piston-cylinder, and belt apparatuses, multianvil devices can compress a sample uniformly from all sides, while achieving a pressure range with an upper limit of at least 30 GPa. All these types of high-pressure apparatuses can be fitted with a resistance heater, typically a sample-surrounding cylinder of graphite or another electrically conducting heating element, for studies at temperatures up to 2,000° C.

THE DIAMOND-ANVIL CELL

The diamond-anvil pressure cell, in which two gem-quality diamonds apply a force to the sample, revolutionized high-pressure research (see Figure 53). The diamond-anvil cell was invented in 1958 almost simultaneously by workers at the National Bureau of Standards in Washington, D.C., and at the University of Chicago. The diamond-cell design represented a logical outgrowth of Bridgman's simple squeezer, but it had one significant advantage over all other high-pressure apparatuses. Diamond, while extremely strong, is also transparent to many kinds of electromagnetic radiation, including gamma rays, X rays, visible light, and much of the infrared and ultraviolet region. The diamond cell thus provided the first opportunity for high-pressure researchers to observe visually the effects of pressure, and it allowed convenient access for many kinds of experimental techniques, notably X-ray diffraction, Mössbauer (gamma-ray), infrared, and Raman spectroscopies, and other optical spectroscopies.

Advantages of diamond cells

The utility of the diamond cell was greatly enhanced when Alvin Van Valkenburg, one of the original diamond-cell inventors at the National Bureau of Standards, placed a thin metal foil gasket between the two diamond-anvil faces. Liquids and other fluid samples could thus be confined in a sample chamber defined by the cylindrical gasket wall and flat diamond ends. In 1963 Van Valkenburg became the first person to observe water, alcohol, and other liquids crystallize at high pressure. The gasketed geometry also permitted for the first time X-ray and optical studies of uncrushed single crystals that were hydrostatically pressurized by a fluid medium.

The diamond-anvil cell holds all records for sustained high pressures. The 100 GPa (megabar) mark was surpassed in December 1975 by the geophysicists Ho-kwang Mao and Peter M. Bell, both of the Geophysical Laboratory of the Carnegie Institution of Washington, in Washington, D.C., where they subsequently attained diamond-cell pressures of approximately 300 GPa. Heating of diamond-cell samples, with both resistance heaters and lasers, has extended accessible pressure-temperature conditions to those that prevail in most of the solid Earth.

The highest transient laboratory pressures are generated with high-velocity projectiles that induce extreme shock pressures (which often reach many millions of atmospheres) for times on the order of one microsecond. Shock waves generated by explosions or gas-propelled projectiles induce dramatic changes in physical properties, as well as rapid polymorphic transformations. Carefully timed intense pulses of X rays or laser light can be used to probe these transient environments. While dynamic high-pressure studies are limited by the difficulty of making precise measurements in such short time periods, these shock techniques have provided insights into changes in atomic structure and properties that occur at extreme conditions. Explosive shock compression has also become an important tool for the synthesis of microcrystalline diamond, which is employed in the polishing of gemstones and other hard materials.

From H.K. Mao and P.M. Bell, "Design of the Diamond-Window, High-Pressure Apparatus for Cryogenic Experiments," *Annual Report of the Director, Geophysical Laboratory, 1978–79*, reprinted from Papers from the Geophysical Laboratory, *Carnegie Institution of Washington Year Book 78*

Physical and chemical effects of high pressure

The principal effect of high pressure, observed in all materials, is a reduction in volume and a corresponding shortening of mean interatomic distances. Coincident with these structural modifications are numerous changes, often dramatic, in physical properties.

Contributions of Bridgman

In four decades of high-pressure research, Bridgman, whose work was honoured by the 1946 Nobel Prize for Physics, documented effects of pressure on electric conductivity, thermal conductivity, viscosity, melting, reaction kinetics, and other material properties. Pressure was found to induce both continuous and discontinuous changes in matter. Bridgman and others observed smoothly varying trends in properties such as electric conductivity or volume versus pressure for most materials. Some substances, however, displayed sharp, reproducible discontinuities in these properties at specific pressures. Dramatic sudden drops in the electric resistance and volume of bismuth, lead, and other metals were carefully documented and provided Bridgman with a useful internal pressure standard for his experiments. These experiments also demonstrated the effectiveness of pressure for studying continuous changes in properties (under uniform compression) and discontinuous changes (phase transitions).

PHASE TRANSITIONS

Under sufficiently high pressure, every material is expected to undergo structural transformations to denser, more closely packed atomic arrangements. At room temperature, for example, all gases solidify at pressures not greater than about 15 GPa. Molecular solids like water ice (H_2O) and carbon tetrachloride (CCl_4) often undergo a series of structural transitions, characterized by successively denser arrangements of molecular units.

A different transition mode is observed in oxides, silicates, and other types of ionic compounds that comprise most rock-forming minerals. In these materials, metal or semimetal atoms such as magnesium (Mg) or silicon (Si) are surrounded by regular tetrahedral or octahedral arrangements of four or six oxygen (O) atoms, respectively. High-pressure phase transitions of such minerals often involve a structural rearrangement that increases the number of oxygen atoms around each central cation. The common mineral quartz (SiO_2), for example, contains four-coordinated silicon at low pressure, but it transforms

to the dense stishovite form with six-coordinated silicon at about 8 GPa. Similarly, the pyroxene mineral with formula $MgSiO_3$ at room pressure contains magnesium and silicon in six- and four-coordination, respectively, but the pyroxene transforms to the perovskite structure with eight-coordinated magnesium and six-coordinated silicon above 25 GPa. Each of these high-pressure phase transitions results in a denser structure with increased packing efficiency of atoms.

High-pressure metallization

The British scientist J.D. Bernal predicted in 1928 that all matter should ultimately become metallic at sufficient pressure, as the forced overlap of electron orbitals induces electron delocalization. High-pressure transformations from insulator to metal were first observed in iodine, silicon, germanium, and other elements by the American chemist Harry G. Drickamer and his coworkers at the University of Illinois at Urbana-Champaign in the early 1960s. Subsequently, metallization has been documented in several more elements (including the gases xenon and oxygen), as well as in numerous molecular, ionic, and covalent chemical compounds. The effort to metallize the element hydrogen at a predicted pressure of several million atmospheres remains a significant challenge in experimental physics.

COMPRESSION

High-pressure X-ray crystallographic studies of atomic structure reveal three principal compression mechanisms in solids: bond compression, bond-angle bending, and intermolecular compression; they are illustrated in Figure 54. Bond compression—*i.e.*, the shortening of interatomic distances—occurs to some extent in all compounds at high pressure. The magnitude of this effect has been shown both theoretically and empirically to be related to bond strength. Strong covalent carbon-carbon bonds in diamond experience the lowest percentage of compression: roughly 0.07 percent per GPa. Similarly, ionic bonds between highly charged cations and anions, such as bonds between

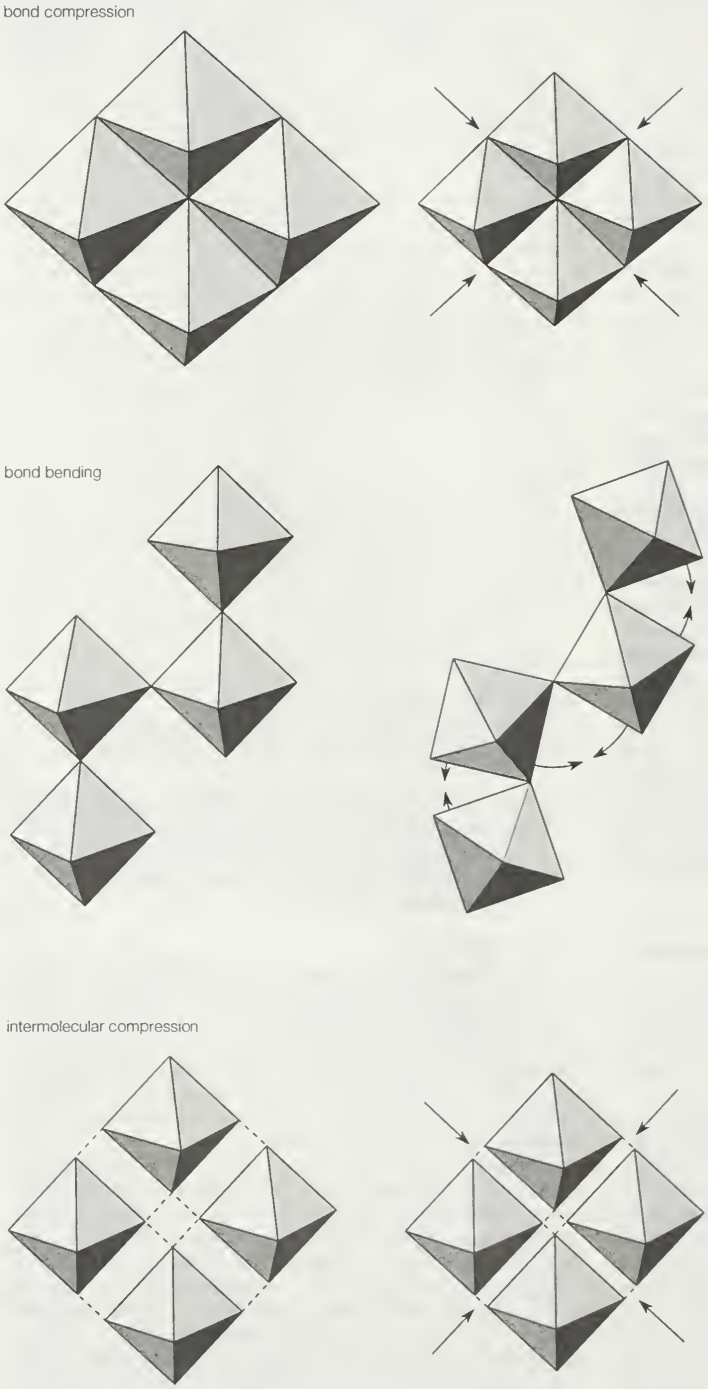

Figure 54: Three compression mechanisms in crystals.

Si^{4+} and O^{2-} in silicates, are relatively incompressible (less than 0.2 percent per GPa). Relatively weak bonds in alkali halides, on the other hand, display bond compressibilities that often exceed 5.0 percent per GPa.

Many common materials display different bonding characteristics in different directions; this occurs notably in layered compounds (*e.g.*, graphite and layered silicates such as micas) and in chain compounds (*e.g.*, many polymeric compounds and chain silicates, including some varieties of asbestos). The strong dependence of bond compression on bond strength thus commonly leads to anisotropies—that is, significant differences in compression in different crystal directions. In many layered-structure silicates, such as mica, in which relatively strong and rigid layers containing magnesium-oxygen, aluminum-oxygen, and silicon-oxygen bonds alternate with weaker layers containing alkali cations, compressibility is five times greater perpendicular to the layers than within the layers. This differential compressibility and the associated stresses that develop in a high-pressure geologic environment contribute to the development of dramatic layered textures in mica-rich rocks such as schist.

Many common ionic compounds, including the rock-forming minerals quartz, feldspar, garnet, zeolite, and perovskite (the high-pressure $MgSiO_3$ form of which is thought to be the Earth's most abundant mineral), are composed of corner-linked clusters—or frameworks—of atomic polyhedrons. A polyhedron consists of a central cation, typically silicon or aluminum in common minerals, surrounded by a regular tetrahedron or octahedron of four or six oxygen atoms, respectively. In framework structures every oxygen atom is bonded to two tetrahedral or octahedral cations, resulting in a three-dimensional polyhedral network. In these materials significant compression can occur by bending the metal-oxygen-metal bond angles between the polyhedrons. The volume change resulting from this bending, and the associated collapse of interpolyhedral spaces, is typically an order of magnitude greater than compression due to bond-length changes alone. Framework structures, consequently, are often much more compressible than structures with only edge- or face-sharing polyhedrons, whose compression is attributable predominantly to bond shortening.

Molecular solids—including ice, solidified gases such as solid oxygen (O_2), hydrogen (H_2), and methane (CH_4), and virtually all organic compounds—consist of an array of discrete, rigid molecules that are linked to one another by weak hydrogen bonds and van der Waals forces. Compression in these materials generally occurs by large decreases in intermolecular distances (often approaching 10 percent per GPa), in contrast to minimal intramolecular compression. Differences in the intermolecular versus intramolecular compression mechanisms lead in some cases to significantly anisotropic compression. Graphite, the low-pressure layered form of elemental carbon in which the "molecules" are continuous two-dimensional sheets, exhibits perhaps the most extreme example of this phenomenon. Carbon-carbon bonds within graphite layers compress only 0.07 percent per GPa (similar to C-C bond compression in diamond), while interlayer compression, dominated by van der Waals forces acting between carbon sheets, is approximately 45 times greater.

Anisotropic compression of graphite

EFFECTS ON ELECTRIC AND MAGNETIC PROPERTIES

The measurement of electric and magnetic properties of materials in a high-pressure environment entails considerable experimental difficulties, especially those associated with attaching leads to pressurized samples or detecting small signals from the experiment. Nevertheless, electric conductivities of numerous materials at high pressures have been documented. The principal classes of solids—insulators, semiconductors, metals, and superconductors—are distinguished on the basis of electric conductivity and its variation with temperature (see above *Solid state*). Insulators, which include most rock-forming oxides and silicates, have been investigated extensively by geophysicists concerned primarily with the behaviour and properties of deep-earth rocks and minerals at extreme conditions. Indeed, it was once hoped that laboratory constraints on such properties could be tied to known values of the Earth's electric and magnetic properties and thus constrain the composition and temperature gradients of Earth models. It appears, however, that small variations in mineral composition (*e.g.*, the ratio of ferrous to ferric iron) as well as defect properties can play a role orders of magnitude greater than that of pressure alone.

Properties of semiconductors are highly sensitive to pressure, because small changes in structure can result in large changes in electronic properties. The metallizations of silicon and germanium, which are accompanied by an orders-of-magnitude increase in electric conductivity, represent extreme cases of such changes. While simple metals display a general trend of increased conductivity with increased pressure, there are many exceptions. Calcium and strontium exhibit maxima in electric conductivity at 30 and 4 GPa, respectively, while barium and arsenic display both maxima and minima with increasing pressure. Ionic conductors, on the other hand, generally experience decreased electric conductivity at high pressure owing to the collapse of ion pathways.

Effects on superconductors

Pressure has been found to be a sensitive probe of the effects of structure on superconductivity, because the structural changes brought about by pressure often have a significant effect on the critical temperature. In simple metals, pressure tends to decrease the critical temperature, eventually suppressing superconductivity altogether. In some organic superconductors, on the other hand, superconductivity appears only at high pressure (and temperatures near absolute zero). In several of the layered copper-oxide high-temperature superconductors, pressure has a strong positive effect on critical temperature; this phenomenon led to the synthesis of new varieties of superconductors in which smaller cations are used to mimic the structural effect of pressure.

The first measurements of magnetic properties at high pressure were conducted on samples in a diamond-anvil cell using Mössbauer spectroscopy, which is a technique that can probe the coupling of a magnetic field with the nuclear magnetic dipole. High-pressure ferromagnetic-to-paramagnetic transitions were documented in iron metal and in magnetite (Fe_3O_4), while Curie temperatures (*i.e.*, the temperature above which the ferromagnetic properties of a material cease to exist) in several metallic elements were found to shift slightly. Subsequent research has employed high-pressure devices constructed of nonmagnetic beryllium-copper alloys, which were developed for research on samples subjected to strong magnetic fields.

Applications

DIAMOND MAKING

While modest pressures (less than 1,000 atm) have long been used in the manufacture of plastics, in the synthesis of chromium dioxide for magnetic recording tape, and in the growth of large, high-quality quartz crystals, the principal application of high-pressure materials technology lies in the synthesis of diamond and other superhard abrasives. Approximately 100 tons of synthetic diamond are produced each year—a weight comparable to the total amount of diamond mined since biblical times. For centuries diamonds had been identified only as an unusual mineral found in river gravels; scientists had no clear idea about their mode of origin until the late 1860s, when South African miners found diamond embedded in its native matrix, the high-pressure volcanic rock called kimberlite. Efforts to make diamond by subjecting graphitic carbon to high pressure began shortly after that historic discovery.

Prior to the work of Bridgman, sufficient laboratory pressures for driving the graphite-to-diamond transition had not been achieved. Bridgman's opposed-anvil device demonstrated that the necessary pressures could be sustained, but high temperatures were required to overcome the kinetic barrier to the transformation. Following World War II, several industrial laboratories, including Allmanna Svenska Elektriska Aktiebolaget (ASEA) in Sweden and Norton Company and General Electric in the United States, undertook major efforts to develop a commercial process. Diamond was first synthesized in a reproducible,

commercially viable experiment in December 1954, when Tracy Hall, working for General Electric, subjected a mixture of iron sulfide and carbon to approximately 6 GPa and 1,500° C in a belt-type apparatus. General Electric employees soon standardized the processes and discovered that a melted ferrous metal, which acts as a catalyst, is essential for diamond growth at these conditions.

EARTH SCIENCE

Synthesis of stishovite

Diamond-making techniques have been embraced by Earth scientists in their efforts to simulate conditions in the Earth's deep interior. Of special significance were the high-pressure syntheses of two new forms of silicates. In 1960 Sergei Stishov, while at the Institute of High-Pressure Physics in Moscow, subjected ordinary beach sand (composed of the mineral quartz SiO_2) to more than 8 GPa of pressure and high temperatures. The form of silica that he produced was approximately 62 percent denser than quartz and was the first known high-pressure compound to contain silicon in six-coordination rather than the four-coordination found in virtually all crustal minerals. The natural occurrence of this new synthetic material was confirmed within a few weeks by careful examination of shocked material from Meteor Crater, Ariz., U.S. The mineral was named stishovite.

In 1974 a second high-pressure discovery revolutionized geologists' understanding of deep-earth mineralogy when Lin-gun Liu of the Australian National University used a diamond-anvil cell to synthesize silicate perovskite, a dense form of the common mineral enstatite, $MgSiO_3$. Subsequent studies by Liu revealed that many of the minerals believed to constitute the deep interior of the Earth transform to the perovskite structure at lower mantle conditions—an observation that led him to propose that silicate perovskite is the Earth's most abundant mineral, perhaps accounting for more than half of the planet's volume. (R.M.Ha.)

BIBLIOGRAPHY

Phase changes. DANIEL S. BARKER, *Igneous Rocks* (1983), ch. 3, "Phase Relations," pp. 24–57, presents a clear summary of the interpretation of petrologic phase diagrams. ERNEST G. EHLERS, *The Interpretation of Geological Phase Diagrams* (1972, reprinted 1987), provides step-by-step nonmathematical procedures for understanding both simple and complex phase diagrams. ERNEST G. EHLERS and HARVEY BLATT, *Petrology: Igneous, Sedimentary, and Metamorphic* (1982), ch. 2, "Experiments with Molten Silicates: Unary and Binary Systems," pp. 43–73, provides an introduction to phase equilibria of petrologic systems. DONALD W. HYNDMAN, *Petrology of Igneous and Metamorphic Rocks* (1972), in the second half of ch. 1, "Environment and Materials," pp. 15–30, summarizes the interpretation of some important petrologic phase diagrams. W.G. ERNST, *Petrologic Phase Equilibria* (1976), is a concise introduction to phase equilibria; some knowledge of thermodynamics on the part of the reader would be helpful. (E.G.E.)

Solid state. General works include LAWRENCE H. VAN VLACK, *Elements of Materials Science and Engineering*, 6th ed. (1989), an elementary textbook; CHARLES A. WERT and ROBB M. THOMSON, *Physics of Solids*, 2nd ed. (1970), an intermediate-level text; CHARLES KITTEL, *Introduction to Solid State Physics*, 6th ed. (1986), the standard college textbook; NEIL W. ASHCROFT and N. DAVID MERMIN, *Solid State Physics* (1976), an advanced textbook; GEORGE E. BACON, *The Architecture of Solids* (1981), an introduction to bonding and structure; and LINUS PAULING, *The Nature of the Chemical Bond and the Structure of Molecules and Crystals*, 3rd ed. (1960, reissued 1989), the classic reference work on chemical bonding.

Crystalline solids: A readable treatment of crystal structure is C.S. BARRETT and T.B. MASSALSKI, *Structure of Metals: Crystallographic Methods, Principles, and Data*, 3rd rev. ed. (1980). RALPH W.G. WYCKOFF, *Crystal Structures*, 2nd ed., 6 vol. (1963–71), compiles information on known structures. Phase diagrams of binary alloys are compiled in T.B. MASSALSKI (ed.), *Binary Alloy Phase Diagrams*, 2nd ed., 3 vol. (1990); and in WILLIAM G. MOFFATT (ed.), *The Handbook of Binary Phase Diagrams*, 4 vol. (1976–), published in a regularly updated looseleaf format. Traditional crystal growing is discussed in J.C. BRICE, *The Growth of Crystals from the Melt* (1965); ALAN COTTRELL, *An Introduction to Metallurgy*, 2nd ed. (1975); and MERTON C. FLEMMINGS, *Solidification Processing* (1974). Epitaxy is discussed by GERALD B. STRINGFELLOW, *Organometallic Vapor Phase Epitaxy: Theory and Practice* (1989); and SEYMOUR P. KELLER (ed.), *Materials, Properties, and Preparation* (1980). WILLIAM SHOCKLEY, *Electrons and Holes in Semiconductors* (1950, reprinted 1976), is an introduction; while RICHARD DALVEN, *Introduction to Applied Solid State Physics*, 2nd ed. (1990), is an intermediate-level text on semiconductors and semiconducting devices. A wealth of information is available in H.H. LANDOLT and R. BÖRNSTEIN, *Zahlenwerte und Funktionen aus Naturwissenschaften und Technik*, new series, ed. by K.H. HELLWEGE, known as *Landolt-Börnstein*, with a parallel title in English, *Numerical Data and Functional Relationships in Science and Technology*, reflecting the two languages of the work; group III, *Kristall- und Festkörperphysik* (or *Crystal and Solid State Physics*), contains compiled measurements of semiconductor properties in vol. 17a–g (1982–85) and resistivity data on all metals and alloys in vol. 15a, pp. 1–289 (1982), and vol. 15b, pp. 1–47 (1985). Books on magnetism are D.H. MARTIN, *Magnetism in Solids* (1967); JOHN E. THOMPSON, *The Magnetic Properties of Materials* (1968); and KENNETH HOPE STEWART, *Ferromagnetic Domains* (1954). Fullerenes are reviewed in a special issue of *Accounts of Chemical Research*, vol. 25, no. 3 (March 1992). (G.D.Ma.)

Quasicrystals: Introductions to the topic are available in DAVID R. NELSON, "Quasicrystals," *Scientific American*, 255(2):43–51 (August 1986); PETER W. STEPHENS and ALAN I. GOLDMAN, "The Structure of Quasicrystals," *Scientific American*, 264(4):44–47, 50–53 (April 1991); and P.J. STEINHARDT, "Icosahedral Solids: A New Phase of Matter?," *Science*, 238(4831):1242–47 (Nov. 27, 1987). MARTIN GARDNER, "Mathematical Games," *Scientific American*, 236(1):110–112, 115–121 (January 1977), discusses Penrose tilings and their remarkable properties. More technically detailed works are D.P. DIVENCENZO and P.J. STEINHARDT (eds.), *Quasicrystals: The State of the Art* (1991); and the series *Aperiodicity and Order*, ed. by MARKO V. JARIĆ (1988–).

Liquid crystals: The history of the field is surveyed by H. KELKER, "History of Liquid Crystals," *Molecular Crystals and Liquid Crystals*, 21(1 and 2):1–48 (May 1973). The Nobel Prize acceptance lecture by P.G. DE GENNES, "Soft Matter," *Reviews of Modern Physics*, 64(3):645–648 (July 1992), sets liquid crystals in a broader scientific context. Discussions of special topics in liquid crystals, frequently at a level close to this article, may be found in the periodical *Condensed Matter News* (bimonthly). More technical presentations are given in P.G. DE GENNES, *The Physics of Liquid Crystals* (1974); S. CHANDRASEKHAR, *Liquid Crystals*, 2nd ed. (1992); and P.S. PERSHAN, *Structure of Liquid Crystal Phases* (1988). Applications of liquid crystals are described in E. KANEKO, *Liquid Crystal TV Displays* (1987); and J. FUNFSCHILLING, "Liquid Crystals and Liquid Crystal Displays," *Condensed Matter News*, 1:12–16 (1991). (M.W.)

Amorphous solids: A lucid introductory text accessible to a nontechnical reader is RICHARD ZALLEN, *The Physics of Amorphous Solids* (1983), with coverage of structural models for the various classes of amorphous solids as well as percolation theory, a modern paradigm for disordered systems. A classic advanced work is N.F. MOTT and E.A. DAVIS, *Electronic Processes in Non-crystalline Materials*, 2nd ed. (1979), which features many of the theoretical contributions of Nobel Laureate coauthor Mott. A text providing a thorough treatment of oxide glasses is J. ZARZYCKI, *Glasses and the Vitreous State* (1991; originally published in French, 1982). A reference work with wide coverage of recent research topics, including detailed treatment of chalcogenide glasses, is S.R. ELLIOTT, *Physics of Amorphous Materials*, 2nd ed. (1990). A comprehensive collection of detailed reviews is contained in R.W. CAHN, P. HAASSEN, and E.J. KRAMER (eds.), *Materials Science and Technology*, vol. 6, *Glasses and Amorphous Materials*, ed. by J. ZARZYCKI (1991), including coverage of glass technology, formation, and structure, oxide glasses, chalcogenide glasses, metallic glasses, polymeric glasses, and the optical, electric, and mechanical properties of glasses. Amorphous silicon is treated in detail in another work, R.A. STREET, *Hydrogenated Amorphous Silicon* (1991). (R.Z.)

Liquid state. J.N. MURRELL and E.A. BOUCHER, *Properties of Liquids and Solutions* (1982), is a short introduction to the physics and chemistry of the liquid state. ROBERT C. REID, JOHN M. PRAUSNITZ, and BRUCE E. POLING, *The Properties of Gases and Liquids*, 4th ed. (1987), focuses on the vapour-liquid transition, as opposed to the solid-liquid transition, and evaluates and illustrates techniques for estimating and correlating properties of gases and liquids, as well as tabulating the properties of 600 compounds. A. BONDI, *Physical Properties of Molecular Crystals, Liquids, and Glasses* (1968), focuses on the solid-liquid transition as opposed to the vapour-liquid transition and describes methods for the characterization of higher-molecular-weight liquids. J.S. ROWLINSON and F.L. SWINTON, *Liquids and Liquid Mixtures*, 3rd ed. (1982), provides a thorough treatment of the physics of fluids and gives some statistical mechanical theories of the equilibrium properties

of simple pure liquids and liquid mixtures; the work also contains a data bibliography and is primarily for research-oriented readers. *Dictionary of Organic Compounds,* 5th ed., 7 vol. (1982), and annual supplements, is a listing of such properties of organic compounds as chemical formula, density, and melting and boiling points; the work is useful for organic chemists in synthesizing and identifying organic compounds. GILBERT NEWTON LEWIS and MERLE RANDALL, *Thermodynamics,* 2nd ed., rev. by KENNETH S. PITZER and LEO BREWER (1961), is a classic text on the thermodynamics of pure substances and solutions, written from the point of view of chemistry. JOHN M. PRAUSNITZ, RUEDIGER N. LICHTENTHALER, and EDMUNDO GOMES DE AZEVEDO, *Molecular Thermodynamics of Fluid-Phase Equilibria,* 2nd ed. (1986), employs molecular-thermodynamic concepts useful for engineering and is written from a chemical-engineering point of view. The first three chapters of K.E. WEALE, *Chemical Reactions at High Pressures* (1967), give a description of the behaviour of pure systems and phase equilibria at very high pressures. JOHN M. PRAUSNITZ *et al., Computer Calculations for Multicomponent Vapor-Liquid and Liquid-Liquid Equilibria* (1980), includes a short, annotated list of literature sources for vapour-liquid and liquid-liquid phase equilibria. (B.E.P.)

Gaseous state. The best elementary discussion of the kinetic theory of gases is T.G. COWLING, *Molecules in Motion* (1960), clearly explaining all the fundamental physical ideas without excessive mathematical manipulation. Other elementary books are JOEL H. HILDEBRAND, *An Introduction to Molecular Kinetic Theory* (1963); SIDNEY GOLDEN, *Elements of the Theory of Gases* (1964); and WALTER KAUZMANN, *Kinetic Theory of Gases* (1966). Two excellent books make greater demands on the mathematical background of the reader: JAMES JEANS, *An Introduction to the Kinetic Theory of Gases* (1940, reissued 1982), which is an abridged and slightly simplified version of the author's classic *The Dynamical Theory of Gases,* 4th ed. (1925, reissued 1954); and RICHARD D. PRESENT, *Kinetic Theory of Gases* (1958), an excellent though selective textbook. The historical literature is especially rich; the following works may be profitably consulted: J.S. ROWLINSON (ed.), *J.D. van der Waals: On the Continuity of the Gaseous and Liquid States* (1988), a translation of van der Waals's 1873 Dutch thesis with a marvelous extended introductory essay by the editor that is unique in the field and surveys modern developments in the theory of liquids and solutions; STEPHEN G. BRUSH (ed.), *Kinetic Theory,* 3 vol. (1965–72), a set of famous historical papers along with introductory commentaries and summaries by the editor; ROBERT LINDSAY (ed.), *Early Concepts of Energy in Atomic Physics* (1979), selections from famous historical papers—many of them omitted from the previous work—together with the editor's comments; and STEPHEN G. BRUSH, *The Kind of Motion We Call Heat: A History of the Kinetic Theory of Gases in the 19th Century,* 2 vol. (1976, reissued 1986), a thorough historical account without much mathematics, and *Statistical Physics and the Atomic Theory of Matter: From Boyle and Newton to Landau and Onsager* (1983), covering a much broader range and requiring a thorough scientific background. More advanced professional treatments include SYDNEY CHAPMAN and T.G. COWLING, *The Mathematical Theory of Non-uniform Gases,* 3rd ed. (1970, reprinted 1990), the acknowledged classic on the modern kinetic theory of gases based on the Enskog-Chapman approach; JOSEPH O. HIRSCHFELDER, CHARLES F. CURTISS, and R. BYRON BIRD, *Molecular Theory of Gases and Liquids* (1954, reissued with added notes 1964), a monumental compendium of detailed results on equations of state, transport properties of gases, and intermolecular forces, especially valuable as a reference; J.H. FERZIGER and H.G. KAPER, *Mathematical Theory of Transport Processes in Gases* (1972), successfully combining the best features of the previous two works; CARLO CERCIGNANI, *The Boltzmann Equation and Its Applications* (1988), by a mathematician, one of the few books that concerns itself with free-molecule gases and the transition to continuum behaviour; and FREDERICK R.W. MCCOURT *et al., Nonequilibrium Phenomena in Polyatomic Gases,* 2 vol. (1990–91), an account of the extension of the Enskog-Chapman theory to include truly molecular shape effects, including the effects of external electric and magnetic fields and of surface collisions. Special topics are addressed in MARTIN KNUDSEN, *The Kinetic Theory of Gases,* 3rd ed. (1950), a series of lectures from 1933 on rarefied gas phenomena, by one of the experimental pioneers in the subject; K.E. GREW and T.L. IBBS, *Thermal Diffusion in Gases* (1952), a short monograph on one of the more intriguing special topics of the kinetic theory of gases; J.S. ROWLINSON, *The Perfect Gas* (1963), emphasizing the internal mechanics of molecules as related to the calculation of the thermodynamic properties of gases by statistical mechanics; and E.A. MASON and T.H. SPURLING, *The Virial Equation of State* (1969), emphasizing experimental measurements and the detailed connection with intermolecular forces. (E.A.M.)

Plasma state. For a general audience an early work that is still of considerable use is LEV A. ARZIMOVICH (L.A. ARTSIMOVICH), *Elementary Plasma Physics* (1965; originally published in Russian, 1963). A more recent work at the same level is YAFFA ELIEZER and SHALOM ELIEZER, *The Fourth State of Matter: An Introduction to the Physics of Plasma* (1989). A broad perspective on plasma physics is provided by NATIONAL RESEARCH COUNCIL (U.S.), PANEL ON THE PHYSICS OF PLASMAS AND FLUIDS, *Plasmas and Fluids* (1986). On the applied side, see NATIONAL RESEARCH COUNCIL (U.S.), PANEL ON PLASMA PROCESSING OF MATERIALS, *Plasma Processing of Materials: Scientific Opportunities and Technological Challenges* (1991). Descriptions of fusion-energy options with a discussion of plasma aspects are included in ROGER A. HINRICHS, *Energy* (1992); and RUTH HOWES and ANTHONY FAINBERG (eds.), *The Energy Sourcebook* (1991). A historical treatment with numerous illustrations dealing with the aurora is ROBERT H. EATHER, *Majestic Lights* (1980). More advanced mid-college-level texts include FRANCIS F. CHEN, *Introduction to Plasma Physics and Controlled Fusion,* vol. 1, *Plasma Physics* (1984); and MICHAEL C. KELLEY and RODNEY A. HEELIS (RODERICK A. HEELIS), *The Earth's Ionosphere: Plasma Physics and Electrodynamics* (1989). (M.C.K.)

Clusters. MICHAEL A. DUNCAN and DENNIS H. ROUBRAY, "Microclusters," *Scientific American,* 261(6):110–115 (December 1989), provides a general introduction and survey for nonscientists. Works presenting the results of recent research include R. STEPHEN BERRY, "When the Melting and Freezing Points Are Not the Same," *Scientific American,* 263(2):68–72, 74 (August 1990), written for nonscientists, a description of the melting and freezing of clusters and their relation to bulk melting and freezing; and several collections of conference proceedings: P. JENA, B.K. RAO, and S.N. KHANNA (eds.), *Physics and Chemistry of Small Clusters* (1987), covering a wide variety of topics within cluster science; S. SUGANO, Y. NISHINA, and S. OHNISHI (eds.), *Microclusters* (1987); G. SCOLES (ed.), *The Chemical Physics of Atomic and Molecular Clusters* (1990), at the graduate-student level; S. SUGANO, *Microcluster Physics* (1991), accessible to scientifically literate readers; and *Zeitschrift für Physik,* part D, vol. 19 and 20 (1991) and vol. 26 (1993), the proceedings of the international conferences on small particles and inorganic clusters held in 1990 and 1992, respectively. (R.S.Be.)

Low-temperature phenomena. F.E. SIMON *et al., Low Temperature Physics: Four Lectures* (1952, reprinted 1961); and K. MENDELSSOHN, *The Quest for Absolute Zero: The Meaning of Low Temperature Physics,* 2nd ed. (1977), are excellent nontechnical summaries. Another account is found in ANTHONY LEGGETT, "Low Temperature Physics, Superconductivity, and Superfluidity," ch. 9 in PAUL DAVIES (ed.), *The New Physics* (1989), pp. 268–288. The *Journal of Low Temperature Physics* (semiannual) contains useful articles. Also informative are *Progress in Low Temperature Physics* (irregular), theoretical and experimental research reports and review articles, all with extensive bibliographies; K. MENDELSSOHN (ed.), *Progress in Cryogenics,* 4 vol. (1959–64), which complements the previous work, with more emphasis on applied problems and developments; FRITZ LONDON, *Superfluids,* vol. 1, *Macroscopic Theory of Superconductivity,* 2nd ed. (1961), and vol. 2, *Macroscopic Theory of Superfluid Helium* (1954, reprinted 1964), the classic presentation of theory; H.M. ROSENBERG, *Low Temperature Solid State Physics: Some Selected Topics* (1963), fairly elementary; MARSHALL SITTIG, *Cryogenics: Research and Applications* (1963); two articles from the *American Journal of Physics,* both by D.M. GINSBERG, "Resource Letter Scy-1 on Superconductivity," 32:85–89 (1964), and "Resource Letter Scy-2 on Superconductivity," 38:949–955 (1970), introductory reviews with descriptive bibliographies; P.G. DE GENNES, *Superconductivity of Metals and Alloys,* trans. from French (1966, reprinted 1989), a presentation of the foundations and applications of the theory; CHARLES G. KUPER, *An Introduction to the Theory of Superconductivity* (1968); WILLIAM E. KELLER, *Helium-3 and Helium-4* (1969), advanced-level summaries of theory; R.D. PARKS (ed.), *Superconductivity,* 2 vol. (1969); W.D. GREGORY, W.N. MATTHEWS, JR., and E.A. FDELSACK (eds.), *The Science and Technology of Superconductivity,* 2 vol. (1973); MICHAEL TINKHAM, *Introduction to Superconductivity* (1975, reprinted 1980), an intermediate introduction; A.C. ROSENNES and E.H. RHODERICK, *Introduction to Superconductivity,* 2nd ed. (1978), basic, with an emphasis on application; GUY K. WHITE, *Experimental Techniques in Low-Temperature Physics,* 3rd ed. (1979, reissued 1987), a detailed discussion; DAVID R. TILLEY and JOHN TILLEY, *Superfluidity and Superconductivity,* 3rd ed. (1990); and DIETER VOLLHARDT and PETER WÖLFLE, *The Superfluid Phases of Helium 3* (1990).

Authoritative review articles of higher-temperature superconductors can be found in D.M. GINSBERG (ed.), *Physical Properties of High Temperature Superconductors,* 3 vol. (1989–92). Other

reports include those by M.K. WU *et al.*, "Superconductivity at 93 K in a New Mixed-Phase Y-Ba-Cu-O Compound System at Ambient Pressure," *Physical Review Letters*, 58(9):908–910 (March 2, 1987); ANIL KHURANA, "Superconductivity Seen Above the Boiling Point of Nitrogen," *Physics Today*, 40(4):17–23 (April 1987); K. ALEX MÜLLER and J. GEORG BEDNORZ, "The Discovery of a Class of High-Temperature Superconductors," *Science*, 237(4819):1133–39 (Sept. 4, 1987); and STUART A. WOLF and VLADIMIR Z. KRESIN, *Novel Superconductivity* (1987). (A.J.L./D.M.Gi.)

High-pressure phenomena. P.W. BRIDGMAN, *The Physics of High Pressure*, new impression with supplement (1949), remains the major source of information on high-pressure history and technology prior to its publication. MAILA L. WALTERS, *Science and Cultural Crisis* (1990), surveys Percy Bridgman's accomplishments. ROBERT M. HAZEN, *The New Alchemists: Breaking Through the Barriers of High Pressure* (1993), reviews the history of high-pressure research, particularly efforts to synthesize diamond. Collected papers from several biannual conferences of the International Association for High-Pressure Research are available in B. VODAR and PH. MARTEAU (eds.), *High Pressure Science and Technology*, 2 vol. (1980); C. HOMAN, R.K. MACCRONE, and E. WHALLEY (eds.), *High Pressure in Science and Technology*, 3 vol. (1984); N.J. TRAPPENIERS *et al.* (eds.), *Proceedings of the Xth AIRAPT International High Pressure Conference on Research in High Pressure Science & Technology* (1986); and W.B. HOLZAPFEL and P.G. JOHANNSEN (eds.), *High Pressure Science and Technology* (1990). Efforts in the Earth sciences are reviewed by S. AKIMOTO and M.H. MANGHNANI (eds.), *High-Pressure Research in Geophysics* (1982); and M.H. MANGHNANI and YASUHIKO SYONO (eds.), *High-Pressure Research in Mineral Physics* (1987). (R.M.Ha.)

Maxwell

James Clerk Maxwell is regarded by most modern physicists as the scientist of the 19th century who had the greatest influence on 20th-century physics; he is ranked with Sir Isaac Newton and Albert Einstein for the fundamental nature of his contributions. In 1931, at the 100th anniversary of Maxwell's birth, Einstein described the change in the conception of reality in physics that resulted from Maxwell's work as "the most profound and the most fruitful that physics has experienced since the time of Newton." The concept of electromagnetic radiation originated with Maxwell, and his field equations, based on Michael Faraday's observations of the electric and magnetic lines of force, paved the way for Einstein's special theory of relativity, which established the equivalence of mass and energy. Maxwell's ideas also ushered in the other major innovation of 20th-century physics, the quantum theory. His description of electromagnetic radiation led to the development (according to classical theory) of the ultimately unsatisfactory law of heat radiation, which prompted Max Planck's formulation of the quantum hypothesis—*i.e.*, the theory that radiant-heat energy is emitted only in finite amounts, or quanta. The interaction between electromagnetic radiation and matter, integral to Planck's hypothesis, in turn has played a central role in the development of the theory of the structure of atoms and molecules.

By courtesy of King's College London

Maxwell, engraving by G.J. Stodart.

Early life. Maxwell came from a comfortable middle-class background. The original family name was Clerk, the additional surname being added by his father after he had inherited the Middlebie estate from Maxwell ancestors. James, an only child, was born on June 13, 1831, in Edinburgh, where his father was a lawyer; his parents had married late in life, and his mother was 40 years old at his birth. Shortly afterward the family moved to Glenlair, the country house on the Middlebie estate.

Education and early contributions

His mother died in 1839 from abdominal cancer, the very disease to which Maxwell was to succumb at exactly the same age. A dull and uninspired tutor was engaged who claimed that James was slow at learning, though in fact he displayed a lively curiosity at an early age and had a phenomenal memory. Fortunately he was rescued by his aunt Jane Cay and from 1841 was sent to school at the Edinburgh Academy. Among the other pupils were his biographer Lewis Campbell and his friend Peter Guthrie Tait.

Maxwell's interests ranged far beyond the school syllabus, and he did not pay particular attention to examination performance. His first scientific paper, published when he was only 14 years old, described a generalized series of oval curves that could be traced with pins and thread by analogy with an ellipse. This fascination with geometry and with mechanical models continued throughout his career and was of great help in his subsequent research.

At the age of 16 he entered the University of Edinburgh, where he read voraciously on all subjects and published two more scientific papers. In 1850 he went to the University of Cambridge, where his exceptional powers began to be recognized. His mathematics teacher, William Hopkins, was a well-known "wrangler maker" (a wrangler is one who takes first class honours in the mathematics examinations at Cambridge) whose students included Tait, George Gabriel (later Sir George) Stokes, William Thomson (later Lord Kelvin), Arthur Cayley, and Edward John Routh. Of Maxwell, Hopkins is reported to have said that he was the most extraordinary man he had met with in the whole course of his experience, that it seemed impossible for him to think wrongly on any physical subject, but that in analysis he was far more deficient. (Other contemporaries also testified to Maxwell's preference for geometrical over analytical methods.) This shrewd assessment was later borne out by several important formulas advanced by Maxwell that obtained correct results from faulty mathematical arguments.

In 1854 Maxwell was second wrangler and first Smith's prizeman (the Smith's prize is a prestigious competitive award for an essay that incorporates original research). He was elected to a fellowship at Trinity, but, because his father's health was deteriorating, he wished to return to Scotland. In 1856 he was appointed to the professorship of natural philosophy at Marischal College, Aberdeen, but before the appointment was announced his father died. This was a great personal loss, for Maxwell had had a close relationship with his father. In June 1858 Maxwell married Katherine Mary Dewar, daughter of the principal of Marischal College. The union was childless and was described by his biographer as a "married life . . . of unexampled devotion."

Career

In 1860 the University of Aberdeen was formed by a merger between King's College and Marischal College, and Maxwell was declared redundant. He applied for a vacancy at the University of Edinburgh, but he was turned down in favour of his school friend Tait. He then was appointed to the professorship of natural philosophy at King's College, London.

The next five years were undoubtedly the most fruitful of his career. During this period his two classic papers on the electromagnetic field were published, and his demonstration of colour photography took place. He was elected to the Royal Society in 1861. His theoretical and experimental work on the viscosity of gases also was undertaken during these years and culminated in a lecture to the Royal Society in 1866. He supervised the experimental determination of electrical units for the British Association for the Advancement of Science, and this work in measurement and standardization led to the establishment of the National Physical Laboratory. He also measured the ratio of electromagnetic and electrostatic units of electricity and confirmed that it was in satisfactory agreement with the velocity of light as predicted by his theory.

Later life. In 1865 he resigned his professorship at King's College and retired to the family estate in Glenlair. He continued to visit London every spring and served as external examiner for the Mathematical Tripos (exams) at Cambridge. In the spring and early summer of 1867 he toured Italy. But most of his energy during this period was devoted to writing his famous treatise on electricity and magnetism.

It was Maxwell's research on electromagnetism that es-

tablished him among the great scientists of history. In the preface to his *Treatise on Electricity and Magnetism* (1873), the best exposition of his theory, Maxwell stated that his major task was to convert Faraday's physical ideas into mathematical form. In attempting to illustrate Faraday's law of induction (that a changing magnetic field gives rise to an induced electromagnetic field), Maxwell constructed a mechanical model. He found that the model gave rise to a corresponding "displacement current" in the dielectric medium, which could then be the seat of transverse waves. On calculating the velocity of these waves, he found that they were very close to the velocity of light. Maxwell concluded that he could "scarcely avoid the inference that light consists in the transverse undulations of the same medium which is the cause of electric and magnetic phenomena."

Research on electromagnetism

Maxwell's theory suggested that electromagnetic waves could be generated in a laboratory, a possibility first demonstrated by Heinrich Hertz in 1887, eight years after Maxwell's death. The resulting radio industry with its many applications thus has its origin in Maxwell's publications.

In addition to his electromagnetic theory, Maxwell made major contributions to other areas of physics. While still in his 20s, Maxwell demonstrated his mastery of classical physics by writing a prizewinning essay on Saturn's rings, in which he concluded that the rings must consist of masses of matter not mutually coherent—a conclusion that was corroborated more than 100 years later by the first Voyager space probe to reach Saturn.

Maxwell's other contributions to science

The Maxwell relations of equality between different partial derivatives of thermodynamic functions are included in every standard textbook on thermodynamics (see THERMODYNAMICS, PRINCIPLES OF). Though Maxwell did not originate the modern kinetic theory of gases, he was the first to apply the methods of probability and statistics in describing the properties of an assembly of molecules. Thus he was able to demonstrate that the velocities of molecules in a gas, previously assumed to be equal, must follow a statistical distribution (known subsequently as the Maxwell-Boltzmann distribution law). In later papers Maxwell investigated the transport properties of gases—*i.e.*, the effect of changes in temperature and pressure on viscosity, thermal conductivity, and diffusion.

Maxwell was far from being an abstruse theoretician. He was skillful in the design of experimental apparatus, as was shown early in his career during his investigations of colour vision. He devised a colour top with adjustable sectors of tinted paper to test the three-colour hypothesis of Thomas Young and later invented a colour box that made it possible to conduct experiments with spectral colours rather than pigments. His investigations of the colour theory led him to conclude that a colour photography could be produced by photographing through filters of the three primary colours and then recombining the images. He demonstrated his supposition in a lecture to the Royal Institution of Great Britain in 1861 by projecting through filters a colour photograph of a tartan ribbon that had been taken by this method.

In addition to these well-known contributions, a number of ideas that Maxwell put forward quite casually have since led to developments of great significance. The hypothetical intelligent being known as Maxwell's demon was a factor in the development of information theory. Maxwell's analytic treatment of speed governors is generally regarded as the founding paper on cybernetics, and his "equal areas" construction provided an essential constituent of the theory of fluids developed by Johannes Diederik van der Waals. His work in geometrical optics led to the discovery of the fish-eye lens. From the start of his career to its finish his papers are filled with novelty and interest. He also was a contributor to the ninth edition of *Encyclopædia Britannica*.

In 1871 Maxwell was elected to the new Cavendish professorship at Cambridge. He set about designing the Cavendish Laboratory and supervised its construction. Maxwell had few students, but they were of the highest calibre and included William D. Niven, Ambrose (later Sir Ambrose) Fleming, Richard Tetley Glazebrook, John Henry Poynting, and Arthur Schuster.

Cavendish Laboratory

During the Easter term of 1879 Maxwell took ill on several occasions; he returned to Glenlair in June but his condition did not improve. He died after a short illness on Nov. 5, 1879. Maxwell received no public honours and was buried quietly in a small churchyard in the village of Parton, in Scotland.

BIBLIOGRAPHY. Maxwell's works include *Theory of Heat*, 3rd ed. (1872, reprinted 1970), and *A Treatise on Electricity and Magnetism*, 3rd ed., 2 vol. (1892, reissued 1954). Maxwell's original papers are collected in W.D. NIVEN (ed.), *The Scientific Papers of James Clerk Maxwell*, 2 vol. (1890, reissued 2 vol. in 1, 1965).

A standard biography is LEWIS CAMPBELL and WILLIAM GARNETT, *The Life of James Clerk Maxwell* (1882, reprinted 1969). Modern biographies include C.W.F. EVERITT, *James Clerk Maxwell: Physicist and Natural Philosopher* (1975), with a useful bibliography; IVAN TOLSTOY, *James Clerk Maxwell* (1981), for the general reader; and MARTIN GOLDMAN, *The Demon in the Aether* (1983). Commemorative publications include J.J. THOMSON *et. al.*, *James Clerk Maxwell: A Commemorative Volume, 1831–1931* (1931), containing lectures given at Cambridge University; CYRIL DOMB (ed.), *Clerk Maxwell and Modern Science* (1963), lectures concerning his electromagnetic theory; and CYRIL DOMB, "James Clerk Maxwell: 100 Years Later," *Nature*, 282:235–239 (Nov. 15, 1979).

More details of his contributions to electromagnetism are in R.A.R. TRICKER, *The Contributions of Faraday and Maxwell to Electrical Science* (1966); EDMUND WHITTAKER, *A History of the Theories of Aether and Electricity*, rev. and enlarged ed., 2 vol. (1951–53, reprinted 1987); and JED Z. BUCHWALD, *From Maxwell to Microphysics: Aspects of Electromagnetic Theory in the Last Quarter of the Nineteenth Century* (1985), exploring Maxwellian theory and the transition into modern field theory.

Measurement Systems

The concept of weights and measures, though it has come in modern times to include temperature, luminosity, pressure, and electric current, once consisted of only four basic measurements: mass (weight), volume (liquid or grain measure), distance, and area. The last three are, of course, closely related.

Basic to the whole idea of weights and measures are the concepts of uniformity, units, and standards. Uniformity, the essence of any system of weights and measures, requires accurate, reliable standards of mass and length and agreed-on units. A unit is the name of a quantity, such as kilogram or pound; a standard is the physical embodiment of a unit, such as the platinum-iridium cylinder kept by the International Bureau of Weights and Measures at Paris as the standard kilogram.

Two types of measurement systems are distinguished historically: an evolutionary system, such as the British Imperial, which grew more or less haphazardly out of custom, and a planned system, such as the present-day International System of Units (SI; Système Internationale d'Unités), in universal use by the world's scientific community and by most nations.

This article surveys the development of some of the world's major measurement systems and their distinctive characteristics. For coverage of related topics in the *Macropædia* and *Micropædia,* see the *Propædia,* section 723, and the *Index.*

This article is divided into the following sections:

EARLY UNITS AND STANDARDS

Ancient Mediterranean systems. Body measurements probably provided the most convenient bases for early linear measurements; early weight units may have derived casually from the use of certain containers or from calculations of what a person or animal could lift or haul.

The historical progression of units has followed a generally westward direction, the units of the ancient empires of the Middle East finding their way, mostly as a result of trade, to the Greek and then the Roman empires, thence to Gaul and Britain via Roman conquest.

The Egyptians. Although there is evidence that many early civilizations devised standards of measurement and some tools for measuring, the Egyptian cubit is generally recognized as having been the most ubiquitous standard of linear measurement in the very ancient world. Developed about 3000 BC, it was based on the length of the arm from the elbow to the extended fingertips and was standardized by a royal master cubit of black granite, against which all the cubit sticks in use in Egypt were measured at regular intervals.

The cubit

The royal cubit (524 millimetres, or 20.62 inches) was subdivided in an extraordinarily complicated way. The basic subunit was the digit, doubtlessly a finger's breadth, of which there were 28 in the royal cubit. Four digits equaled a palm, five a hand. Twelve digits, or three palms, equaled a small span. Fourteen digits, or one-half a cubit, equaled a large span. Sixteen digits, or four palms, made one *t'ser.* Twenty-four digits, or six palms, were a small cubit.

The digit was in turn subdivided. The 14th digit on a cubit stick was marked off into 16 equal parts. The next digit was divided into 15 parts, and so on, to the 28th digit, which was divided into 2 equal parts. Thus, measurement could be made to digit fractions with any denominator from 2 through 16. The smallest division, $1/16$ of a digit, was equal to $1/448$ part of a royal cubit.

The accuracy of the cubit stick is attested by the dimensions of the Great Pyramid of Giza; although thousands were employed in building it, its sides vary no more than 0.05 percent from the mean length of 230.364 metres (9,069.45 inches).

The Egyptians developed methods and instruments for measuring land at a very early date. The annual flood of the Nile River created a need for benchmarks and surveying techniques so that property boundaries could be readily reestablished when the water receded.

The Egyptian weight system appears to have been founded on a unit called the *kite,* with a decimal ratio, 10 *kites* equaling 1 *deben,* and 10 *debens* equaling 1 *sep.* Over the long span of Egyptian history, the weight of the *kite* varied from period to period, ranging all the way from 4.5 to 29.9 grams (0.16 to 1.05 ounce). About 3,400 different weights have been recovered from ancient Egypt, some in basic geometric shapes, others in human and animal forms.

Egyptian liquid measures, from large to small, were *ro, hin, hekat, khar,* and cubic cubit (0.14 cubic metre [37 U.S. gallons]).

The Babylonians. The earliest of all known weights is possibly the Babylonian mina, which in one surviving form weighed about 640 grams (23 ounces) and in another about 978 grams (34 ounces). Archaeologists have also found weights of 5 minas, in the shape of a duck, and a 30-mina weight in the form of a swan. The shekel, familiar from the Bible as a standard Hebrew coin and weight, was originally Babylonian. Most of the Babylonian weights and measures, carried in commerce throughout the Middle East, were gradually adopted by other countries. The basic Babylonian unit of length was the *kus* (about 530 millimetres, or 20.9 inches), also called the Babylonian cubit. The Babylonian *shusi,* defined as $1/30$ *kus,* was equal to 17.5 millimetres (0.69 inch). The Babylonian foot was $2/3$ *kus.*

Earliest known weights

The Babylonian liquid measure, *ka,* was the volume of a cube of one handbreadth (99 to 102 millimetres, or 3.9 to 4 inches). The cube, however, had to contain a weight of one great mina of water. The *ka* was a subdivision of two other units; 300 *ka* equaled 60 *gin* and 1 *gur.* The *gur* represented a volume of almost 303 litres (80 U.S. gallons).

The Hittites, Assyrians, Phoenicians, and Hebrews derived their systems generally from the Babylonians and Egyptians. Hebrew standards were based on the relationship between the mina, the talent (the basic unit), and the shekel. The sacred mina was equal to 60 shekels, and the sacred talent to 3,000 shekels, or 50 sacred minas. The Talmudic mina equaled 25 shekels; the Talmudic talent equaled 1,500 shekels, or 60 Talmudic minas.

The volumes of the several Hebrew standards of liquid measure are not definitely known; the *bat* may have contained about 37 litres (nearly 10 U.S. gallons); if so, the *log* equaled slightly more than 0.5 litre (0.13 U.S. gallon), and the *hin* slightly more than 6 litres (1.6 U.S. gallons). The Hebrew system was notable for the close relationship between dry and liquid volumetric measures; the liquid kor was the same size as the dry homer, and the liquid *bat* corresponded to the dry *'efa.*

Greeks and Romans. In the 1st millennium BC, commercial domination of the Mediterranean passed into the hands of the Greeks first and then the Romans. A basic

Early Greek units of measurement

Greek unit of length was the finger (19.3 millimetres, or 0.76 inch); 16 fingers equaled 30 centimetres (1 foot), and 24 fingers equaled 1 Olympic cubit. The coincidence with the Egyptian 24 digits equaling 1 small cubit suggests what is altogether probable on the basis of the commercial history of the era, that the Greeks derived their measures partly from the Egyptians and partly from the Babylonians, probably via the Phoenicians. The Greeks apparently used linear standards to establish their primary liquid measure, the *metrētēs,* equivalent to 39.4 litres (10.4 U.S. gallons). A basic Greek unit of weight was the talent (equal to 25.8 kilograms, or 56.9 pounds), obviously borrowed from Eastern neighbours.

The Romans, adapting the Greek system, subdivided the foot into 12 ounces, or inches (unciae), using the same word and the same subdivision, unciae, for $^1/_{12}$ pound (libra), which equaled 327.45 grams. The Romans made five feet equal to one pace, or double step, 1,000 of which made up the Roman mile (*mille passus*). The *sextarius* (0.53 litre, or 0.14 U.S. gallon) was the basic Roman unit of volume; it had several subdivisions and multiples, of which the largest, the amphora, borrowed from the Greeks, was 48 *sextarii* (25.5 litres, or 6.7 U.S. gallons).

The ancient Chinese system. Completely separated from the Mediterranean-European history of metrology is that of ancient China; yet the Chinese system exhibits all the principal characteristics of the Western. It employed parts of the body as a source of units—for example, the distance from the pulse to the base of the thumb. It was fundamentally chaotic in that there was no relationship between different types of units, such as those of length and those of volume. Finally, it was rich in variations. The *mou,* a unit of land measure, fluctuated from region to region from 0.08 to 0.13 hectare (0.2 to 0.3 acre). Variations were not limited to the geographic; a unit of length with the same name might be of one length for a carpenter, another for a mason, and still another for a tailor.

Shih huang-ti, who became the first emperor of China in 221 BC, is celebrated for, among other things, his unification of the regulations fixing the basic units. The basic weight, the *shih,* or *tan,* was fixed at about 60 kilograms (132 pounds); the two basic measurements, the *chih* and the *chang,* were set at about 25 centimetres (9.8 inches) and 3 metres (9.8 feet), respectively. A noteworthy characteristic of the Chinese system, and one that represented a substantial advantage over the Mediterranean systems, was its predilection for a decimal notation, as demonstrated by foot rulers dating back as far as the 6th century BC. Measuring instruments, too, were of a high order.

A unique characteristic of the Chinese system was its inclusion of an acoustic dimension. A standard vessel used for measuring grain and wine was defined not only as to weight but also as to pitch when struck; given a uniform shape and fixed weight, only a vessel of the proper volume would give the proper pitch. Thus the same word in old Chinese means "wine bowl," "grain measure," and "bell." Measures based on the length of a pitch pipe and its subdivision in terms of millet grains supplanted the old measurements based on the human body. The change brought a substantial increase in accuracy.

Medieval systems. Medieval Europe inherited the Roman system, with its Greek, Babylonian, and Egyptian roots. It soon proliferated through daily use and language variations into a great number of national and regional variants, with elements borrowed from Scandinavia and from the Arabs and original contributions growing out of the needs of medieval commerce.

Charlemagne's attempts to achieve standardization

A determined effort by Charlemagne to impose uniformity at the beginning of the 9th century was in vain; differing usages hardened. The great trade fairs, such as the Champagne Fairs of the 12th and 13th centuries, enforced rigid uniformity on merchants of all nationalities within the fairgrounds and had some effect on standardizing differences among regions, but the variations remained. A good example is the ell, the universal measure for wool cloth, the great trading staple of the Middle Ages. The ell of Champagne, two feet six inches, measured against an iron standard in the hands of the Keeper of the Fair, was accepted by Ypres and Ghent, both in modern Belgium; by Arras, in modern France; and by the other great cloth-manufacturing cities of northwest Europe, even though their bolts varied in length. In several other parts of Europe, the ell itself varied, however.

The basic Roman unit of weight, the libra, acquired a Germanic name in parts of northern Europe but retained its Roman identity in the English abbreviation of pound as lb. Similarly the Roman mile survived, while the pace on which it was based vanished; it ceased to be a thousand of anything and instead became varying numbers of feet and yards, measures inherited from earlier northern Europe.

Medieval liquid measure was generally based on the *pinte,* or pint, which was approximately equal to the modern English quart; the quart was a medieval unit of dry measure, very close to its modern English equivalent in volume.

THE ENGLISH AND U.S. CUSTOMARY WEIGHTS AND MEASURES SYSTEMS

The English system. Out of the welter of medieval weights and measures emerged several national systems, reformed and reorganized from time to time; ultimately nearly all these were replaced by metric. In Britain and its American colonies, however, the ancient system survived.

By the time of Magna Carta (1215), abuses of weights and measures were so common that a clause was inserted in the charter to correct those on grain and wine. A few years later a royal ordinance entitled "Assize of Weights and Measures" defined a broad list of units and standards so successfully that it remained in force for nearly 600 years. A standard yard, "the Iron Yard of our Lord the King," was prescribed for the realm, divided into the traditional 3 feet, each of 12 inches, "neither more nor less." The perch (later the rod) was defined as 5.5 yards, or 16.5 feet. The inch was subdivided into 3 barley corns.

The furlong (a "furrow long") was eventually standardized as an eighth of a mile; the acre, probably from an old Anglo-Saxon word, as an area 4 rods wide by 40 long.

Troy and avoirdupois weights

The influence of the Champagne Fairs may be seen in the separate English pounds for troy weight, probably from Troyes, one of the principal fair cities, and avoirdupois, the term used at the fairs for goods that had to be weighed—sugar, salt, alum, dyes, grain. The troy pound, for weighing gold and silver bullion and apothecaries' drugs, contained only 12 troy ounces.

A multiple of the English pound was the stone, which added a fresh element of confusion to the system by equaling neither 12 nor 16 but 14 pounds. The sacks of raw wool, which were medieval England's principal export, weighed 26 stones, or 364 pounds; huge standards, weighing 91 pounds, or one-fourth a sack, were employed in wool weighing. The sets of standards, which were sent out from London to the provincial towns, were usually of bronze or brass. Discrepancies somehow crept into the system, and in 1496, following a Parliamentary inquiry, new standards were made and sent out, a procedure repeated in 1588, under Elizabeth I.

No revision of law was found necessary for 200 years after Elizabeth's time, but several refinements and redefinitions were added. Edmund Gunter, a 17th-century mathematician, conceived the idea of taking the acre's breadth (4 perches, or 22 yards), calling it a chain, and dividing it into 100 links. In 1701 the corn bushel in dry measure was defined as "any round measure with a plain and even bottom, being 18.5 inches wide throughout and 8 inches deep." Similarly, in 1707 the wine gallon was defined as a round measure with an even bottom and containing 231 cubic inches; however, the ale gallon was retained at 282 cubic inches. There was also a corn gallon and an older, slightly smaller wine gallon.

A new Weights and Measures Act of 1824 sought to clear away some of the medieval tangle. A single gallon was decreed, defined as the volume occupied by "10 imperial pounds weight of distilled water weighed in air against brass weights with the water and the air at a temperature of 62 degrees of Fahrenheit's thermometer and with the barometer at 30 inches."

The same definition was reiterated in the Act of 1878, which redefined the yard: "the straight line or distance between the centres of two gold plugs or pins in the bronze

bar . . . measured when the bar is at the temperature of sixty-two degrees of Fahrenheit's thermometer, and when it is supported by bronze rollers placed under it in such a manner as best to avoid flexure of the bar."

By an act of Parliament in 1963, all the English weights and measures were redefined in terms of the metric system, with a national changeover beginning two years later.

The U.S. customary system. In his first message to Congress in 1790, George Washington drew attention to the need for "uniformity in currency, weights and measures." Currency was settled in a decimal form, but the vast inertia of the English weights and measures system permeating industry and commerce and involving containers, measures, tools, and machines, as well as popular psychology, prevented the same approach, though it was advocated by Thomas Jefferson, from succeeding. In these very years the metric system was coming into being in France, and in 1821 Secretary of State John Quincy Adams, in a famous report to Congress, called the metric system "worthy of acceptance . . . beyond a question." Yet Adams admitted the impossibility of winning acceptance for it in the United States, until a future time "when the example of its benefits, long and practically enjoyed, shall acquire that ascendancy over the opinions of other nations which gives motion to the springs and direction to the wheels of the power."

Differences between the English and U.S. systems

Instead of adopting metric, the United States tried to bring its system into closer harmony with the English, from which various deviations had developed; for example, the United States still used "Queen Anne's gallon" of 231 cubic inches, which the British had discarded in 1824. Construction of standards was undertaken by the Office of Standard Weights and Measures, under the Treasury Department. The standard for the yard was one imported from London some years earlier, which guaranteed a close identity between the American and English yard; but Queen Anne's gallon was retained. The avoirdupois pound, at 7,000 grains, exactly corresponded with the British, as did the troy pound at 5,760 grains; however, the U.S. bushel, at 2,150.42 cubic inches, again deviated from the British. The U.S. bushel was derived from the "Winchester bushel," a surviving standard dating to the 15th century, which had been replaced in the British Act of 1824. It might be said that the U.S. gallon and bushel, smaller by about 17 percent and 3 percent, respectively, than the British, remain more truly medieval than their British counterparts.

At least the standards were fixed, however. From the mid-19th century, new states, as they were admitted to the Union, were presented with sets of standards. Late in the century, pressure grew to enlarge the role of the Office of Standard Weights and Measures, which, by Act of Congress effective July 1, 1901, became the National Bureau of Standards (since 1988 the National Institute of Standards and Technology), part of the Commerce Department. Its functions, as defined by the Act of 1901, included, besides the construction of physical standards and cooperation in establishment of standard practices, such activities as developing methods for testing materials and structures; carrying out research in engineering, physical science, and mathematics; and compilation and publication of general scientific and technical data. One of the first acts of the bureau was to sponsor a National Conference on Weights and Measures to coordinate standards among the states; one of the main functions of the annual conference became the updating of a model state law on weights and measures, which resulted in virtual uniformity in legislation.

Apart from this action, however, the U.S. government remained unique among major nations in refraining from exercising control at the national level. One noteworthy exception was the Metric Act of 1866, which permitted use of the metric system in the United States.

THE METRIC SYSTEM OF MEASUREMENT

The development and establishment of the metric system. One of the most significant results of the French Revolution was the establishment of the metric system of weights and measures.

European scientists had for many years discussed the desirability of a new, rational, and uniform system to replace the national and regional variants that made scientific communication difficult. The first proposal to closely approximate what eventually became the metric system was made as early as 1670. Gabriel Mouton, the vicar of St. Paul's Church in Lyon, suggested a length measure based on the arc of one minute of longitude, to be subdivided decimally. Mouton's proposal contained three of the major characteristics of the metric system: decimalization, rational prefixes, and the Earth's measurement as basis for a definition. Mouton's proposal was discussed, amended, criticized, and advocated for 120 years before the fall of the Bastille and the creation of the National Assembly made it a political possibility. In April of 1790 one of the foremost members of the assembly, Talleyrand, introduced the subject and launched a debate that resulted in a directive to the French Academy of Sciences to prepare a report. After several months' study, the academy recommended that the length of the meridian passing through Paris be determined from the North Pole to the Equator, that 1/10,000,000 of this distance be termed the metre and form the basis of a new decimal linear system, and, further, that a new unit of weight should be derived from the weight of a cubic metre of water. A list of prefixes for decimal multiples and submultiples was proposed. The National Assembly endorsed the report and directed that the necessary meridional measurements be taken.

The work of Gabriel Mouton

On June 19, 1791, a committee of 12 mathematicians, geodesists, and physicists met with Louis XVI, who gave his formal approval. The next day, the king attempted to escape from France, was arrested, returned to Paris, and was imprisoned; a year later, from his cell, he issued the proclamation that directed two engineers, Jean Delambre and Pierre Méchain, to perform the operations necessary to determine the length of the metre. The intervening time had been spent by the scientists and engineers in preliminary research; Delambre and Méchain now set to work to measure the distance on the meridian from Barcelona, Spain, to Dunkirk in northern France. The survey proved arduous; civil and foreign war so hampered the operation that it was not completed for six years. While Delambre and Méchain were struggling in the field, administrative details were being worked out in Paris. In 1793 a provisional metre was constructed from geodetic data already available. In 1795 the firm decision was taken to enact adoption of the metric system for France. The new law defined the length, mass, and capacity standards and listed the prefixes for multiples and submultiples. With the formal presentation to the assembly of the standard metre, as determined by Delambre and Méchain, the metric system became a fact in June 1799. The motto adopted for the new system was "For all people, for all time."

Establishment of the metric system

The standard metre was the Delambre-Méchain survey-derived "one ten-millionth part of a meridional quadrant of the earth." The gram, the basic unit of mass, was made equal to the mass of a cubic centimetre of pure water at the temperature of its maximum density (4° C [39.2° F]). A platinum cylinder known as the Kilogram of the Archives was declared the standard for 1,000 grams.

The litre was defined as the volume equivalent to the volume of a cube, each side of which had a length of 1 decimetre, or 10 centimetres.

The are was defined as the measure of area equal to a square 10 metres on a side. In practice the multiple hectare, 100 ares, became the principal unit of land measure.

The stere was defined as the unit of volume, equal to one cubic metre.

Names for multiples and submultiples of all units were made uniform, based on Greek prefixes.

The metric system's conquest of Europe was facilitated by the military successes of the French Revolution and Napoleon, but it required a long period of time to overcome the inertia of customary systems. Even in France Napoleon found it expedient to issue a decree permitting use of the old medieval system. Nonetheless, in the competition between the two systems existing side by side, the advantages of the metric proved decisive; in 1840 it was established as the legal monopoly in France, and from

Table 1: Elemental and Derived SI Units and Symbols

quantity	SI units		
	unit	formula	symbol
Elemental units			
Length	metre	—	m
Mass	kilogram	—	kg
Time	second	—	s
Electric current	ampere	—	A
Temperature	kelvin	—	K
Luminous intensity	candela	—	cd
Plane angle	radian	—	rad
Solid angle	steradian	—	sr
Derived units			
Acceleration	metre/second squared	m/s^2	
Area	square metre	m^2	
Capacitance	farad	$A \cdot s/V$	F
Charge	coulomb	$A \cdot s$	C
Density	kilogram/cubic metre	kg/m^3	
Electric field strength	volt/metre	V/m	
Energy	joule	$N \cdot m$	J
Force	newton	$kg \cdot m/s^2$	N
Frequency	hertz	s^{-1}	Hz
Illumination	lux	lm/m^2	lx
Inductance	henry	$V \cdot s/A$	H
Kinematic viscosity	square metre/second	m^2/s	
Luminance	candela/square metre	cd/m^2	
Luminous flux	lumen	$cd \cdot sr$	lm
Magnetic field strength	ampere/metre	A/m	
Magnetic flux	weber	$V \cdot s$	Wb
Magnetic flux density	tesla	Wb/m^2	T
Power	watt	J/s	W
Pressure	pascal (newton/square metre)	N/m^2	Pa
Resistance	ohm	V/A	Ω
Stress	pascal (newton/square metre)	N/m^2	Pa
Velocity	metre/second	m/s	
Viscosity	newton-second/square metre	$N \cdot s/m^2$	
Voltage	volt	W/A	V
Volume	cubic metre	m^3	

that point forward its progress through the world has been steady, though it is worth observing that in many cases metric was adopted during the course of a political upheaval, just as in its original French beginning. Notable examples are Latin America, the Soviet Union, and China. In Japan the adoption of metric came about following the peaceful but far-reaching political changes associated with the Meiji Restoration of 1868.

In Britain, the Commonwealth nations, and the United States, the progress of metric has been discernible. The United States became a signatory to the Metric Convention of 1875 and received copies of the International Prototype Metre and the International Prototype Kilogram in 1890. Three years later the Office of Weights and Measures announced that the prototype metre and kilogram would be regarded as fundamental standards from which the customary units, the yard and the pound, would be derived.

Increasing adoption of the metric system in the 20th century

Throughout the 20th century, use of the metric system in various segments of commerce and industry increased spontaneously in Britain and the United States; it became almost universally employed in the scientific and medical professions. The automobile, electronics, chemical, and electric power industries have all adopted metric at least in part, as have such fields as optometry and photography. Legislative proposals to adopt metric generally have been made in the U.S. Congress and British Parliament. In 1968 Congress passed legislation calling for a program of investigation, research, and survey to determine the impact on the United States of increasing worldwide use of the metric system. The program concluded with a report to Congress in July 1971 that recommended: "on the basis of evidence marshalled in the U.S. metric study, this report [D.V. Simone, "A Metric America, A Decision whose Time has Come," *National Bureau of Standards Special Publication 345*] recommends that the United States change to the International Metric System through a coordinated national program over a period of ten years, at the end of which the nation will be predominantly metric." Parliament went further and established a long-range program of changeover.

In the meantime the metric system itself was replaced by the new International System of Units, which is fundamentally an expansion of 18th-century metric to incorporate scientific and technological developments of the 20th century.

The International System of Units. Just as the original conception of the metric system had grown out of the problems scientists encountered in dealing with the medieval system, so the new International System grew out of the problems a vastly enlarged scientific community faced in the proliferation of subsystems improvised to serve particular disciplines. At the same time, it had long been known that the original 18th-century standards were not accurate to the degree demanded by 20th-century scientific operations; new definitions were required. After lengthy discussion the 11th General Conference on Weights and Measures (11th CGPM), meeting in Paris, birthplace of

the metric system, in October 1960 formulated a new International System of Units (abbreviated SI). The SI was amended by subsequent convocations of the CGPM. The following base units have been adopted and defined:

Base units of SI measurement

Length: metre. Since 1983 the metre has been defined as the distance traveled by light in a vacuum in 1/299,792,458 second.

Mass: kilogram. The standard for the unit of mass, the kilogram, is a cylinder of platinum-iridium alloy kept by the International Bureau of Weights and Measures, located in Sèvres, near Paris. A duplicate in the custody of the National Institute of Standards and Technology serves as the mass standard for the United States. (This is the only base unit still defined by an artifact.)

Time: second. The second is defined as the duration of 9,192,631,770 cycles of the radiation associated with a specified transition, or change in energy level, of the cesium-133 atom.

Electric current: ampere. The ampere is defined as the magnitude of the current that, when flowing through each of two long parallel wires separated by one metre in free space, results in a force between the two wires (due to their magnetic fields) of 2×10^{-7} newton (the newton is a unit of force equal to about 0.2 pound) for each metre of length.

Thermodynamic temperature: kelvin. The thermodynamic, or Kelvin, scale of temperature used in SI has its origin or zero point at absolute zero and has a fixed point at the triple point of water (the temperature and pressure at which ice, liquid water, and water vapour are in equilibrium), defined as 273.16 kelvins. The Celsius scale is derived from the Kelvin scale. The triple point is defined as 0.01° on the Celsius scale, which is approximately 32.02° on the Fahrenheit scale.

Amount of substance: mole. The mole is defined as the amount of substance containing the same number of chemical units (atoms, molecules, ions, electrons, or other specified entities or groups of entities) as exactly 12 grams of carbon-12.

Light (luminous) intensity: candela. The candela is defined as the luminous intensity in a given direction of a source that emits monochromatic radiation at a frequency of 540×10^{12} hertz and that has a radiant intensity in the same direction of 1/683 watt per steradian (unit solid angle).

BIBLIOGRAPHY. The understanding and development of systems of physical measurements, from early elementary to sophisticated modern ones, are discussed in A.E. BERRIMAN, *Historical Metrology: A New Analysis of the Archaeological and the Historical Evidence Relating to Weights and Measures* (1953, reprinted 1969); B.D. ELLIS, *Basic Concepts of Measurement* (1966); BRUNO KISCH, *Scales and Weights: A Historical Outline* (1965); KEITH ELLIS, *Man and Measurement* (1973); H. ARTHUR KLEIN, *The World of Measurements: Masterpieces, Mysteries, and Muddles of Metrology* (1974; reissued 1988 as *The Science of Measurement: A Historical Survey*); OWEN BISHOP, *Yardsticks of the Universe* (1984); O.A.W. DILKE, *Mathematics and Measurement* (1987); and WITOLD KULA, *Measures and Men* (1986; originally published in Polish, 1970).

Advance toward modern systems of measurement is traced in ARTHUR E. KENNELLY, *Vestiges of Pre-Metric Weights and Measures Persisting in Metric-System Europe, 1926–1927* (1928); *Landmarks in Metrology—1983* (1983), a collection of papers written in the third quarter of the 20th century and published in connection with an international conference on the subject; REXMOND C. COCHRANE, *Measures for Progress: A History of the National Bureau of Standards* (1966, reprinted 1976), emphasizing the extent of NBS involvement in 20th-century scientific progress; C. DOUGLAS WOODWARD, *BSI—The Story of Standards* (1972), on the work of the British Standards Institution; LAL C. VERMAN, *Standardization, a New Discipline* (1973); and E.L. DELLOW, *Measuring and Testing in Science and Technology* (1970).

Development and maintenance of the U.S. customary system in particular are discussed in RALPH W. SMITH, *The Federal Basis for Weights and Measures: A Historical Review of Federal Legislative Effort, Statutes, and Administrative Action in the Field of Weights and Measures in the United States* (1958); L.J. CHISHOLM, *Units of Weight and Measure: International (Metric) and U.S. Customary* (1967, reprinted 1974), especially interesting for its tables of conversion equivalents; and LEWIS V. JUDSON, *Weights and Measures Standards of the United States: A Brief History* (1976).

Useful reference information, in dictionary or table form, is compiled in STEPHEN DRESNER, *Units of Measurement: An Encyclopaedic Dictionary of Units, Both Scientific and Popular, and the Quantities They Measure* (1971); JOHN L. FEIRER, *SI Metric Handbook* (1977); H.G. JERRARD and D.B. MCNEILL, *A Dictionary of Scientific Units: Including Dimensionless Numbers and Scales*, 5th ed. (1986); J.V. DRAZIL, *Quantities and Units of Measurement: A Dictionary and Handbook* (1983); and *The World Measurement Guide: Editorial Information Compiled by THE ECONOMIST*, 4th rev. ed. (1980).

Current research and development in the field is reported in such periodicals as *M & C: Measurements & Control* (bimonthly, U.S.); *Measurement and Control* (monthly, Great Britain); *Measurement Science & Technology* (monthly); and *Measurement: Journal of the International Measurement Confederation* (quarterly).

(L.J.C./Ed.)

Mecca and Medina

Mecca and Medina are the most sacred cities of Islām. Muḥammad, known to Muslims as the Prophet, was born in Mecca, and, according to Islāmic tradition, it was while living there that he received the first divine revelations leading him to the foundation of Islām. It is toward the city's sacred shrine, the Kaʿbah, that Muslims turn five times daily in prayer, and it is to this destination that all devout Muslims are obliged to attempt a pilgrimage, or hajj (Arabic: *ḥajj*), at least once in their lives. Medina is celebrated as the place in which Muḥammad founded the first Muslim community after his migration, or Hegira (Arabic: *hijrah*), from Mecca (AD 622) and from which he conquered all of Arabia in his war against the polytheists of Mecca. A lesser pilgrimage is made to Muḥammad's tomb, adjacent to the Prophet's mosque in Medina.

The two cities are situated in west-central Saudi Arabia in a region known as the Hejaz, and, separated by some 250 miles (400 kilometres), Medina lies due north of Mecca. The two have been traditionally identified with one another since the time of Muḥammad, and, because of their sacred features, only Muslims are allowed to enter their precincts.

This article is divided into the following sections:

MECCA

The holiest of Muslim cities, Mecca (Arabic: Makkah) is located in the Ṣirāt Mountains inland from the Red Sea coast of Saudi Arabia. The city has an area of about 10 square miles (26 square kilometres).

A historic city closely tied to tradition, Mecca has benefited from the Saudi Arabian oil economy of the 20th century, although income from the hajj is still important. The city has undergone vast improvements. The area around the religious shrines has been cleared; the mosque has been enlarged; housing and sanitation have been improved; and transportation facilities have been enhanced. As a result, Mecca can accommodate the continually increasing number of pilgrims, or hajjis.

Physical and human geography

THE LANDSCAPE

The city site. Mecca is situated at an elevation of 909 feet (277 metres) above sea level in the dry beds of the Wādī Ibrāhīm and several of its short tributaries. It is surrounded by the Ṣirāt Mountains, the peaks of which include Mount (Jabal) Ajyad, which rises to 1,332 feet, and Mount Abū Qubays, which attains 1,220 feet, to the east and Mount Quʿayqʿān, which reaches 1,401 feet, to the west. Mount Hirāʾ rises to 2,080 feet on the northeast and contains a cave in which Muḥammad sought isolation and visions before he became a prophet. It was also in this cave that he received the first verse (*āyah*) of the holy Qurʾān. South of the city is Mount Thawr (2,490 feet), which contains the cave in which the Prophet secreted himself from his Meccan enemies during the Hegira to Medina, the event that marks the beginning of the Muslim calendar.

Entrance to the city is gained through four gaps in the surrounding mountains. The passes lead from the northeast to Minā, ʿArafāt, and Aṭ-Ṭāʾif; from the northwest to Medina; from the west to Jiddah; and from the south to Yemen (Ṣanʿāʾ). The gaps have also defined the direction of the contemporary expansion of the city.

Climate. Because of its relatively low-lying location, Mecca is threatened by seasonal flash floods despite the low amount of annual precipitation. Less than five inches (130 millimetres) of rain falls during the year, mainly in the winter months. Temperatures are high throughout the year and in summer may reach 113° F (45° C).

Plant and animal life. Plant and animal life are scarce and consist of species that can withstand the high degree of aridity and heat. Natural vegetation is sparse and includes tamarisks and various types of acacia. Wild animals in the vicinity include wild cats, wolves, hyenas, foxes, mongooses, and kangaroo rats (jerboas).

Mecca's religious shrines

The city layout. The city centres on the Ḥaram Mosque (the Great Mosque), in which are situated the Kaʿbah and the sacred well of Zamzam. The compact built-up area around the mosque comprises the old city, which stretches to the north and southwest but is limited on the east and west by the nearby mountains. The main avenues are Al-Muddaʿah and Sūq al-Layl to the north of the mosque and As-Sūq as-Saghīr to the south.

Since World War II, Mecca has expanded along the roads through the mountain gaps to the north, northwest, and west. Among the modern residential areas are Al-ʿAzīzīyah and Al-Faysalīyah along the road to Minā and Aẓ-Ẓāhir, Az-Zahraʾā, and Shāriʿ al-Manṣūr along the roads to Jiddah and Medina. Expansion has been accompanied by the construction of new streets in the old city and by the transformation of Mecca into a modern city, with fountains, built since the 1950s, in its four main squares. The Ḥaram Mosque is magnificent in its size and architecture and has been embellished and enlarged on numerous occasions throughout the centuries, most recently in a massive expansion by the government of Saudi Arabia in the 1980s and '90s. The state-of-the-art complex, now multilevel, includes an advanced communication network, air condi-

tioning, escalators, and a complex network of pedestrian routes and tunnels, in addition to numerous aesthetic and artistic accompaniments. The mosque can accommodate one million worshippers at a time. Houses near the mosque have been razed, and it is now surrounded by open spaces and wide streets, which can be crossed through underground walkways, built to ease traffic.

Housing. Mecca's houses are more compacted in the old city than in the modern residential areas. Traditional buildings of two or three stories are built of local rock. The villas in the modern areas are constructed of concrete. Slum conditions can still be found in various parts of the city; the slum inhabitants are mainly poor pilgrims who, unable to finance their return home, remained in Mecca after arriving either for the hajj or for a lesser pilgrimage known as the *ʿumrah.*

THE PEOPLE

The population density in Mecca is high. Most of the people are concentrated in the old city, while densities in the modern residential areas are the lowest in the city.

During the month of pilgrimage, the city is swollen with between one million and two million worshippers from other parts of the country and from other Muslim nations.

Entrance into Mecca is permitted only to followers of Islām. It is, however, one of the most cosmopolitan cities in the world, containing people from the various countries throughout the world. People of the same national origin tend to live together in certain parts of the city.

THE ECONOMY

Arable land and water are scarce, and food must be imported. Vegetables and fruits are brought in daily from the surrounding wadis, such as Wādī Fāṭimah, from the Aṭ-Ṭāʾif area to the east-southeast, and from the southern agricultural areas, such as Bilād Ghāmid and Bilād Zahrān. Foodstuffs are imported from abroad mainly through the port of Jiddah, about 45 miles (70 kilometres) to the west on the Red Sea.

Industry. Industry is limited and includes the manufacture of textiles, furniture, and utensils. The overall urban economy is commercial and service-oriented.

Transportation. Transportation and facilities related to the hajj are the main services. Mecca has no airport or water or rail services. It is well served, however, by the Jiddah seaport and airport and by intercity truck, bus, and taxi services. A local bus system was established in 1979. Paved roads link Mecca with the main cities of Saudi Arabia and neighbouring countries.

The problems of the pilgrimage

Because of the improvement of services, the number of pilgrims has increased. This annual influx brings a good income to the city, but it also results in a temporary population of some two million or more, all of whom need accommodations, food, water, electricity, transportation, and medical services. To answer the problem of accommodations, the Saudi government has erected huge tent cities each year for the hajj, although sporadic fires in these camps have caused a number of deaths.

In accordance with the prescribed route, all pilgrims have to be transported from Mecca to ʿArafāt, a distance of nearly 12 miles, during the early morning of the ninth day of the month of Dhū al-Ḥijjah. During the night of the same day, they must travel to Minā, which is almost two miles from Mecca; after three days, all are returned to Mecca. This problem has been met by the construction of a good road network, an adequate supply of vehicles, and traffic control.

ADMINISTRATION AND SOCIAL CONDITIONS

Government. The governor of the city is the emir of Makkah *minṭaqah idārīyah* (administrative district), who is responsible for the maintenance of law and order in both the city and the *minṭaqah;* he is appointed by the king and is immediately responsible to the minister of the interior. The municipal council is responsible for the functioning of the municipality; the council was formed after World War II and has 14 members, who are locally elected and are then approved by the minister of the interior. Mecca is also the capital of Makkah *minṭaqah idārīyah,* which includes the cities of Jiddah and Aṭ-Ṭāʾif.

Public utilities. Mecca depends on the surrounding wadis for drinking water. The waters of Zubaydah Spring (ʿAyn Zubaydah), built in the 8th century, flow through tunnels from Wādī Nuʿmān, about 20 miles to the southwest. Al-ʿAzīzīyah Spring sends its waters through pipelines from Wādī ash-Shāmīyah, about 60 miles to the northeast. Water and electricity have reached almost all houses. Electricity is generated at an oil-fueled power station located on the road to Medina.

Education services

Education. Free education is provided for both girls and boys from primary to university level. The Umm al-Qura University (founded 1979) is located in Mecca, as are two university colleges—the Madrasat Ahl al-Hadith and the Saudi Arabian Institute for Higher Education.

Health. Health services and medical care are free and adequate. Despite careful checking by officials, pilgrims may sometimes bring various illnesses, particularly cholera and cerebrospinal infections, into the city; the health services, however, have been able to keep such problems under control.

History

Ancient Mecca was an oasis on the old caravan trade route that linked the Mediterranean world with South Arabia, East Africa, and South Asia. The town was located about midway between Maʾrib in the south and Petra in the north, and it gradually developed by Roman and Byzantine times into an important trade and religious centre. It was known to Ptolemy as Macoraba.

According to Islāmic tradition, Abraham and Ishmael, his son by Hagar, built the Kaʿbah as the house of God. The central point of pilgrimage in Mecca before the advent of Islām in the 7th century, the cube-shaped stone building has been destroyed and rebuilt several times. During pre-Islāmic times, the city was ruled by a series of Yemeni tribes. Under the Quraysh, it became a type of city-state, with strong commercial links to the rest of Arabia, Ethiopia, and Europe. Mecca became a place for trade, for pilgrimage, and for tribal gatherings.

The city gained its religious importance with the birth of Muḥammad about 570. The prophet was forced to flee from Mecca in 622, but he returned eight years later and took control of the city. He purged Mecca of idols, declared it a centre of Muslim pilgrimage, and dedicated it to God. Since then, the city has remained the major religious centre of Islām. As the ancient caravan route fell into decline, Mecca lost its commercial significance, and it has since lived mainly on the proceeds from the annual pilgrimages and the gifts of Muslim rulers. (A.S.A./Ed.)

The Ottoman period

Mecca was sacked by the Umayyad general al-Ḥajjāj ibn Yūsuf, and thereafter the city acknowledged the power of the Umayyad caliphate at Damascus and, following the eclipse of that dynasty, of the ʿAbbāsid caliphate of Baghdad. The city suffered great indignity at the hands of the Shīʿite Qarmatians in 930 when that sect's leader Ṭāhir Sulaymān pillaged Mecca and carried off the Black Stone from the Kaʿbah. Beginning in the mid-10th century, the local city rulers were chosen from the sharifs, or descendants of Muḥammad, who retained a strong hold on the surrounding area while often paying homage to stronger political entities. The ability of the sharifs, originally moderate Shīʿites, to adapt to the changing political and religious climate ensured their preeminence in local affairs for the next 1,000 years. In 1269 Mecca came under the control of the Egyptian Mamlūk sultans. In 1517 dominion over the holy city passed to the Ottoman Empire, with its capital in Constantinople (now Istanbul). With the Ottoman collapse after World War I, control of Mecca was contested between the sharifs and the Āl Saʿūd (the Saʿūd family) of central Arabia, adherents to an austere, puritanical form of Islām known as Wahhābism. King Ibn Saʿūd entered the city in 1925, and it became part of the Kingdom of Saudi Arabia and the capital of Makkah *minṭaqah idārīyah.*

Under Saudi rule, Wahhābism was enforced as the state credo, and the facilities for pilgrims were improved. Mecca underwent extensive economic development as Saudi Arabia's petroleum resources were exploited after World

War II, and the number of yearly pilgrims exploded. Despite lavish expenditures by the Saudi government to renovate the city and mosque area, in terms of both beauty and safety, the overwhelming crush of pilgrims each year has led to tragedy on several occasions, as in 1990, when nearly 1,500 pilgrims were trampled in a pedestrian tunnel, and in 1997, when several hundred died in a tent city fire and ensuing panic.

Political turmoil and violence have also often plagued the city. In 1979 a group of militants, mostly Saudi but many from other Islāmic countries, seized the Ḥaram Mosque and were evicted only with great loss of life after an assault by the Saudi National Guard. During the 1980s and '90s, Iranian pilgrims frequently engaged in political protests that led to clashes with Saudi police. Many deaths and injuries also ensued. (Ed.)

MEDINA

Medina (Arabic: Al-Madīnah) was known as Yathrib before the Prophet Muḥammad's residence there. The name was thereafter changed to Madīnat Rasūl Allāh ("City of the Messenger of God") or Al-Madīnah al-Munawwarah ("the Luminous City"). The city is situated in the Hejaz region of western Saudi Arabia, about 250 miles (400 kilometres) north of Mecca and 85 miles inland from the Red Sea. Medina is second only to Mecca as the holiest place of Islām.

Physical and human geography

THE LANDSCAPE

The city site. Medina lies some 2,000 feet (600 metres) above sea level on a fertile oasis. It is bounded on the east by an extensive lava field, part of which dates from a volcanic eruption in AD 1207. On the other three sides, the city is enclosed by arid hills belonging to the Hejaz mountain range. The highest of these hills is Mount Uḥud, which rises to more than 2,000 feet above the oasis.

The city layout. Medina is a sacred area, and only Muslims are permitted to enter the city. The airport, however, lies just outside the sacred limits, and a good view of the city can be obtained by foreigners from aircraft landing at the airport.

In Turkish times, there was a small military landing ground at Sultanah, to the south near the garrison's barricks, but the area is now occupied by the king's palace and its extensive satellites. There too are the ruins of the tomb of ʿAmr ibn al-ʿĀṣ, the celebrated conquerer of Palestine and Egypt in early Islāmic times. Other religious features of the oasis include the mosque of Qubāʾ, the first in Islāmic history; the Mosque of the Two Qiblahs, commemorating the change of the prayer direction from Jerusalem to Mecca, at Ar-Rimāḥ; the tomb of Ḥamzah, uncle of the Prophet, and of his companions who fell in the Battle of Uḥud (625), in which the Prophet was wounded; and the cave in the flank of Uḥud in which the Prophet took refuge on that occasion. Other mosques commemorate where he donned his armour for that battle; where he rested on the way thither, and where he unfurled his standard for the battle of the ditch (*khandaq*); and the ditch itself, dug around Medina by Muḥammad, in which the rubble of the great fire during the reign of Sultan Abdülmecid I (1839–61) was dumped. All these spots are the object of pious visitation by all Muslims visiting Medina; they are forbidden to non-Muslims. In addition, the city is also the site of the Islāmic University, established in 1961.

But the cynosure of all pilgrims is the Prophet's Mosque, which Muḥammad himself helped to build. Additions and improvements were undertaken by a succession of caliphs, and the chamber of the Prophet's wives was merged in the extension during the time of the Umayyad caliph al-Walīd ibn ʿAbd al-Malik. Fire twice damaged the mosque, first in 1256 and again in 1481, and its rebuilding was variously undertaken by devout rulers of several Islāmic countries. Sultan Selim II (1566–74) decorated the interior of the mosque with mosaics overlaid with gold. Sultan Muḥammad built the dome in 1817 and in 1839 painted it green, this being the accepted colour of Islām. Sultan Abdülmecid I initiated a project for the virtual reconstruction of the mosque in 1848 and completed it in 1860. A modern expansion was planned by King ʿAbdul-ʿAziz in 1948 and executed by King Saʿūd in 1953–55. This renovation included the construction of a new northern court with its surrounding colonnades, all in the same style as the 19th-century building but of concrete instead of stone from the neighbouring hills. The *Qafaṣ* (cage), to which female worshippers were formerly restricted, was dismantled, while, apart from minor repairs, the southern (main) part of the mosque remained intact. At its core, the mosque comprises the three ornamental iron structures representing the houses of the Prophet and containing, respectively (according to general consensus), the tomb of the Prophet himself under the great green dome, those of the first two caliphs (Abū Bakr and ʿUmar), and that of the Prophet's daughter Fāṭimah. A specially adorned section of the pillared southern colonnade represents the palm grove (Ar-Rawḍah) in which the first simple mosque was built. In the 1980s and '90s, the government of Saudi Arabia lavished attention on the mosque, adding such accoutrements as state-of-the-art sliding domes, staircases, escalators, and an additional level for increased prayer space. The mosque is now equipped with an air-conditioning and shading system and an expansive logistic and transportation network. In addition, numerous aesthetic and structural embellishments were made; the mosque now has the capacity to hold roughly one million worshippers at a time.

Medina's modernization has not been so rapid as that of Jiddah, Riyadh, and other Saudi towns. In order to make room for new construction, the old city wall had to be completely dismantled, and that historic area had to merged with the now built-up pilgrim camping ground (Al-Manākh) and the Anbārīyah quarter, beyond the Abū-Jidāʿ torrent bed, which was formerly the commercial quarter and in which the Turks established the railway station and terminal yards. The foundations of the old city wall were found to be lower than the surface of accumulated silt and rubble; however, no attempt has been made to examine the excavations from an archaeological point of view. Nor has any archaeological work been done on the ruined sites of the old Jewish settlements, the largest of which was Yathrib (the Lathrippa or Iathrippa of Ptolemy and Stephanus Byzantius), which gave its name to the entire oasis until Islāmic times. There are also several interesting mounds (*ʿitm*), besides the village of Al-Qurayẓah, which would certainly produce historical data of interest. The Islāmic cemetery of Al-Baqīyah was shorn of all the domes and ornamentation of the tombs of the saints at the time of the Wahhābī conquest of 1925; simple concrete graves in place of the old monuments and a circuit wall have been installed.

THE PEOPLE

The residents of Medina are Arabic-speaking Muslims, most of whom belong to the Sunnite branch of Islām. The city is one of the most populous in Saudi Arabia, and it is common for Muslims who make the pilgrimage to settle in the city. Farming and pottery making are important occupations.

THE ECONOMY

Agriculture. To supplement the income derived from accommodating pilgrims, Medina has an economy based on the cultivation of fruits, vegetables, and cereals. The city is especially well known for its date palms, the fruits of which are processed and packaged for export at a plant built in 1953.

Mechanical pumps for irrigation, in use since Turkish times early in the 20th century, have virtually replaced the old draw wells. Drinking water is supplied by an aqueduct from a spring at the southern end of the oasis. In addition

to the plentiful supply of subsoil water at no great depth, a number of important wadis meet in the vicinity of Medina and bring down torrents of water during the winter rains. Of these the most notable are the Wādī al-ʿAqīq from the western mountains and a wadi coming down from the Aṭ-Ṭāʾif area to the south.

Industry. Although Medina was known in early Islāmic times for metalworking, jewelry, and armoury, these industries were never large-scale, and most activity was connected with agricultural technology until the mid-20th century. Principal activities include automobile repair, brick and tile making, carpentry, and metalworking.

Transportation. From 1908 to 1916 Medina was connected with Damascus by the Hejaz railway, destroyed during World War I. Reconstruction of this railroad is studied periodically but has never taken place. Asphalt roads link the city with Jiddah, Mecca, and Yanbuʿ (Medina's port on the Red Sea); another road extends north through the Hejaz and connects the city to Jordan. Al-Jiladain airport nearby provides transportation to Saudi Arabian centres and has links to Jordan, Egypt, and Syria.

History

The earliest history of Medina is obscure, though it is known that there were Jewish settlers there in pre-Christian times. But the main influx of Jews is thought to have taken place as the result of their expulsion from Palestine by the Roman emperor Hadrian in about AD 135. It is probable that the Arab tribes of Aws and Khazraj were then in occupation of the oasis, but the Jews were the dominant factor in the population and development of the area by AD 400. On Sept. 20, 622, the arrival of the Prophet Muḥammad at Medina, in flight from Mecca, introduced a new chapter into the history of the oasis. Soon after the Hegira, tensions developed between the Jewish and Muslim communities, and the major Jewish groups were driven from the region. Medina became the administrative capital of the steadily expanding Islāmic state, a position it maintained until 661, when it was superseded in that role by Damascus, the capital of the Umayyad caliphs.

The flight from Mecca

After the caliph's sack of the city in 683 for its fractiousness, the native emirs enjoyed a fluctuating measure of independence, interrupted by the aggressions of the sharifs of Mecca or controlled by the intermittent Egyptian protectorate.

The Ottomans, following their conquest of Egypt, held Medina after 1517 with a firmer hand, but their rule weakened and was almost nominal long before the Wahhābīs, an Islāmic revivalist group, first took the city in 1804. A Turko-Egyptian force retook it in 1812, and the Turks remained in effective control until the revival of the Wahhābī movement under Ibn Saʿūd after 1912. Between 1904 and 1908 the Turks built the Hejaz railroad to Medina from Damascus in an attempt at strengthening the empire and ensuring Ottoman control over the hajj, the obligatory Muslim pilgrimage to the nearby holy city of Mecca. Turkish rule ceased during World War I, when Ḥusayn ibn ʿAlī, the sharif of Mecca, revolted and put the railroad out of commission, with the assistance of the British officer T.E. Lawrence ("Lawrence of Arabia"). Ḥusayn later came into conflict with Ibn Saʿūd, and in 1925 the city fell to the Saʿūd dynasty. (J.B.Gl./Ed.)

BIBLIOGRAPHY. Literature about Mecca is available mainly in Arabic. For pre-Islāmic and early Islāmic times, see M.A.A. AL-AZRAQI, *Akhbār Makkah*, written in the 9th century (1875, reprinted 1969); and A.I. AL-SHARIF, *Makkah wa-al-Madīnah* (1965). Mechanics: Energy, Forces, and Their Effects

Mechanics is the science concerned with the motion of bodies under the action of forces, including the special case in which a body remains at rest. Of first concern in the problem of motion are the forces that bodies exert on one another. This leads to the study of such topics as gravitation, electricity, and magnetism, according to the nature of the forces involved. Given the forces, one can seek the manner in which bodies move under the action of forces; this is the subject matter of mechanics proper.

Historically, mechanics was among the first of the exact sciences to be developed. Its internal beauty as a mathematical discipline and its early remarkable success in accounting in quantitative detail for the motions of the Moon, the Earth, and other planetary bodies had enormous influence on philosophical thought and provided impetus for the systematic development of science into the 20th century.

Mechanics may be divided into three branches: statics, which deals with forces acting on and in a body at rest; kinematics, which describes the possible motions of a body or system of bodies; and kinetics, which attempts to explain or predict the motion that will occur in a given situation. Alternatively, mechanics may be divided according to the kind of system studied. The simplest mechanical system is the particle, defined as a body so small that its shape and internal structure are of no consequence in the given problem. More complicated is the motion of a system of two or more particles that exert forces on one another and possibly undergo forces exerted by bodies outside of the system.

The principles of mechanics have been applied to three general realms of phenomena. The motions of such celestial bodies as stars, planets, and satellites can be predicted with great accuracy thousands of years before they occur. (The theory of relativity predicts some deviations from the motion according to classical, or Newtonian, mechanics; however, these are so small as to be observable only with very accurate techniques, except in problems involving all or a large portion of the detectable universe.) As the second realm, ordinary objects on Earth down to microscopic size (moving at speeds much lower than that of light) are properly described by classical mechanics without significant corrections. The engineer who designs bridges or aircraft may use the Newtonian laws of classical mechanics with confidence, even though the forces may be very complicated, and the beautifully simple and precise calculations of celestial mechanics usually cannot be duplicated. The third realm of phenomena comprises the behaviour of matter and electromagnetic radiation on the atomic and subatomic scale. Although there were some limited early successes in describing the behaviour of atoms in terms of classical mechanics, these phenomena are properly treated in quantum mechanics.

This article treats the fundamental parameters and concepts of classical mechanics and of certain key allied fields. It also considers those of quantum mechanics in some detail.

For coverage of related topics in the *Macropædia* and *Micropædia*, see the *Propædia*, sections 126–131, and the *Index*. (Ed.)

The article is divided into the following sections:

CLASSICAL MECHANICS

Classical mechanics deals with the motion of bodies under the influence of forces or with the equilibrium of bodies when all forces are balanced. The subject may be thought of as the elaboration and application of basic postulates first enunciated by Isaac Newton in his *Philosophiae Naturalis Principia Mathematica* (1687), commonly known as the *Principia*. These postulates, called Newton's laws of motion, are set forth below. They may be used to predict with great precision a wide variety of phenomena ranging from the motion of individual particles to the interactions of highly complex systems. A variety of these applications are discussed in this article.

In the framework of modern physics, classical mechanics can be understood to be an approximation arising out of the more profound laws of quantum mechanics and the theory of relativity. However, that view of the subject's place greatly undervalues its importance in forming the context, language, and intuition of modern science and scientists. Our present-day view of the world and man's place in it is firmly rooted in classical mechanics. Moreover, many ideas and results of classical mechanics survive and play an important part in the new physics.

Central concepts in classical mechanics

The central concepts in classical mechanics are force, mass, and motion. Neither force nor mass is very clearly defined by Newton, and both have been the subject of much philosophical speculation since Newton. Both of them are best known by their effects. Mass is a measure of the tendency of a body to resist changes in its state of motion. Forces, on the other hand, accelerate bodies, which is to say, they change the state of motion of bodies to which they are applied. The interplay of these effects is the principal theme of classical mechanics.

Although Newton's laws focus attention on force and mass, three other quantities take on special importance because their total amount never changes. These three quantities are energy, (linear) momentum, and angular momentum. Any one of these can be shifted from one body or system of bodies to another. In addition, energy may change form while associated with a single system, appearing as kinetic energy, the energy of motion; potential energy, the energy of position; heat, or internal energy, associated with the random motions of the atoms or molecules composing any real body; or any combination of the three. Nevertheless, the total energy, momentum, and angular momentum in the universe never changes. This fact is expressed in physics by saying that energy, momentum, and angular momentum are conserved. These three conservation laws arise out of Newton's laws, but Newton himself did not express them. They had to be discovered later.

It is a remarkable fact that, although Newton's laws are no longer considered to be fundamental, nor even exactly correct, the three conservation laws derived from Newton's laws—the conservation of energy, momentum, and angular momentum—remain exactly true even in quantum mechanics and relativity. In fact, in modern physics, force is no longer a central concept, and mass is only one of a number of attributes of matter. Energy, momentum, and angular momentum, however, still firmly hold centre stage. The continuing importance of these ideas inherited from classical mechanics may help to explain why this subject retains such great importance in science today.

The origins and foundations of mechanics

HISTORY

The discovery of classical mechanics was made necessary by the publication, in 1543, of the book *On the Revolutions of the Celestial Spheres* by the Polish astronomer Nicolaus Copernicus. The book was about revolutions, real ones in the heavens, and it sparked the metaphorically named scientific revolution that culminated in Newton's *Principia* about 150 years later. The scientific revolution would change forever how people think about the universe.

In his book, Copernicus pointed out that the calculations needed to predict the positions of the planets in the night sky would be somewhat simplified if the Sun, rather than the Earth, were taken to be the centre of the universe (by which he meant what is now called the solar system). Among the many problems posed by Copernicus' book was an important and legitimate scientific question: if the Earth is hurtling through space and spinning on its axis as Copernicus' model prescribed, why is the motion not apparent?

To the casual observer, the Earth certainly seems to be solidly at rest. Scholarly thought about the universe in the centuries before Copernicus was largely dominated by the philosophy of Plato and Aristotle. According to Aristotelian science, the Earth was the centre of the universe. The four elements—earth, water, air, and fire—were naturally disposed in concentric spheres, with earth at the centre, surrounded respectively by water, air, and fire. Outside these were the crystal spheres on which the heavenly bodies rotated. Heavy, earthy objects fell because they sought their natural place. Smoke would rise through air, and bubbles through water for the same reason. These were natural motions. All other kinds of motion were violent motion and required a proximate cause. For example, an oxcart would not move without the help of an ox.

Aristotelian view of the universe

When Copernicus displaced the Earth from the centre of the universe, he tore the heart out of Aristotelian mechanics, but he did not suggest how it might be replaced. Thus, for those who wished to promote Copernicus' ideas, the question of why the motion of the Earth is not noticed took on a special urgency. Without suitable explanation, Copernicanism was a violation not only of Aristotelian philosophy but also of plain common sense.

The solution to the problem was discovered by the Italian mathematician and scientist Galileo Galilei. Inventing experimental physics as he went along, Galileo studied the motion of balls rolling on inclined planes. He noticed that, if a ball rolled down one plane and up another, it would seek to regain its initial height above the ground, regardless of the inclines of the two planes. That meant, he reasoned, that, if the second plane were not inclined at all but were horizonal instead, the ball, unable to regain its original height, would keep rolling forever. From this observation he deduced that bodies do not need a proximate cause to stay in motion. Instead, a body moving in the horizontal direction would tend to stay in motion unless something interfered with it. This is the reason that the Earth's motion is not apparent; the surface of the Earth and everything on and around it are always in motion together and therefore only seem to be at rest.

This observation, which was improved upon by the French philosopher and scientist René Descartes, who altered the concept to apply to motion in a straight line, would ultimately become Newton's first law, or the law of inertia. However, Galileo's experiments took him far beyond even this fundamental discovery. Timing the rate of descent of the balls (by means of precision water clocks and other ingenious contrivances) and imagining what would happen if experiments could be carried out in the absence of air resistance, he deduced that freely falling bodies would be uniformly accelerated at a rate independent of their mass. Moreover, he understood that the

motion of any projectile was the consequence of simultaneous and independent inertial motion in the horizontal direction and falling motion in the vertical direction. In his book *Dialogues Concerning the Two New Sciences* (1638), Galileo wrote,

> It has been observed that missiles and projectiles describe a curved path of some sort; however, no one has pointed out the fact that this path is a parabola. But this and other facts, not few in number or less worth knowing, I have succeeded in proving . . . .

Galileo's description of motion

Just as Galileo boasted, his studies would encompass many aspects of what is now known as classical mechanics, including not only discussions of the law of falling bodies and projectile motion but also an analysis of the pendulum, an example of harmonic motion. His studies fall into the branch of classical mechanics known as kinematics, or the description of motion. Although Galileo and others tried to formulate explanations of the causes of motion, the focus of the field termed dynamics, none would succeed before Newton.

Galileo's fame during his own lifetime rested not so much on his discoveries in mechanics as on his observations of the heavens, which he made with the newly invented telescope about 1610. What he saw there, particularly the moons of Jupiter, either prompted or confirmed his embrace of the Copernican system. At the time, Copernicus had few other followers in Europe. Among those few, however, was the brilliant German astronomer and mathematician Johannes Kepler.

Kepler devoted much of his scientific career to elucidating the Copernican system. Although Copernicus had put the Sun at the centre of the solar system, his astronomy was still rooted in the Platonic ideal of circular motion. Before Copernicus, astronomers had tried to account for the observed motions of heavenly bodies by imagining that they rotated on crystal spheres centred on the Earth. This picture worked well enough for the stars but not for the planets. To "save the appearances" (fit the observations) an elaborate system emerged of circular orbits, called epicycles, on top of circular orbits. This system of astronomy culminated with the *Almagest* of Ptolemy, who worked in Alexandria in the 2nd century AD. The Copernican innovation simplified the system somewhat, but Copernicus' astronomical tables were still based on circular orbits and epicycles. Kepler set out to find further simplifications that would help to establish the validity of the Copernican system.

In the course of his investigations, Kepler discovered the three laws of planetary motion that are still named for him. Kepler's first law says that the orbits of the planets are ellipses, with the Sun at one focus. This observation swept epicycles out of astronomy. His second law stated that, as the planet moved through its orbit, a line joining it to the Sun would sweep out equal areas in equal times. For Kepler, this law was merely a rule that helped him make precise calculations for his astronomical tables. Later, however, it would be understood to be a direct consequence of the law of conservation of angular momentum. Kepler's third law stated that the period of a planet's orbit depended only on its distance from the Sun. In particular, the square of the period is proportional to the cube of the semimajor axis of its elliptical orbit. This observation would suggest to Newton the inverse-square law of universal gravitational attraction.

By the middle of the 17th century, the work of Galileo, Kepler, Descartes, and others had set the stage for Newton's grand synthesis. Newton is thought to have made many of his great discoveries at the age of 23, when in 1665–66 he retreated from the University of Cambridge to his Lincolnshire home to escape from the bubonic plague. However, he chose not to publish his results until the *Principia* emerged 20 years later. In the *Principia*, Newton set out his basic postulates concerning force, mass, and motion. In addition to these, he introduced the universal force of gravity, which, acting instantaneously through space, attracted every bit of matter in the universe to every other bit of matter, with a strength proportional to their masses and inversely proportional to the square of the distance between them. These principles, taken together, accounted not only for Kepler's three laws and Galileo's falling bodies and projectile motions but also for other phenomena, including the precession of the equinoxes, the oscillations of the pendulum, the speed of sound in air, and much more. The effect of Newton's *Principia* was to replace the by-then discredited Aristotelian worldview with a new, coherent view of the universe and how it worked. The way it worked is what is now referred to as classical mechanics.

Great contributions of Newton

FUNDAMENTAL CONCEPTS

Units and dimensions. Quantities have both dimensions, which are an expression of their fundamental nature, and units, which are chosen by convention to express magnitude or size. For example, a series of events have a certain duration in time. Time is the dimension of the duration. The duration might be expressed as 30 minutes or as half an hour. Minutes and hours are among the units in which time may be expressed. One can compare quantities of the same dimensions, even if they are expressed in different units (an hour is longer than a minute). Quantities of different dimensions cannot be compared with one another.

The fundamental dimensions used in mechanics are time, mass, and length. Symbolically, these are written as t, m, and l, respectively. The study of electromagnetism adds an additional fundamental dimension, electric charge, or q. Other quantities have dimensions compounded of these. For example, speed has the dimensions distance divided by time, which can be written as l/t, and volume has the dimensions distance cubed, or l^3. Some quantities, such as temperature, have units but are not compounded of fundamental dimensions.

There are also important dimensionless numbers in nature, such as the number $\pi = 3.14159\ldots$. Dimensionless numbers may be constructed as ratios of quantities having the same dimension. Thus, the number π is the ratio of the circumference of a circle (a length) to its diameter (another length). Dimensionless numbers have the advantage that they are always the same, regardless of what set of units is being used.

Governments have traditionally been responsible for establishing and enforcing standard units for the sake of orderly commerce, navigation, science, and, of course, taxation. Today all such units are established by international treaty, revised every few years in light of scientific findings. The units used for most scientific measurements are those designated the International System of Units (Système International d'Unités), or SI for short. They are based on the metric system, first adopted officially by France in 1795. Other units, such as those of the British engineering system, are still in use in some places, but these are now defined in terms of the SI units.

Units of length

The fundamental unit of length is the metre. A metre used to be defined as the distance between two scratch marks on a metal bar kept in Paris, but it is now much more precisely defined as the distance that light travels in a certain time interval (1/299,792,458 of a second). By contrast, in the British system, units of length have a clear human bias: the foot, the inch (the first joint of the thumb), the yard (distance from nose to outstretched fingertip), and the mile (one thousand standard paces of a Roman legion). Each of these is today defined as some fraction or multiple of a metre (one yard is nearly equal to one metre). In the SI or the metric system, lengths are expressed as decimal fractions or multiples of a metre (a millimetre = one-thousandth of a metre; a centimetre = one-hundredth of a metre; a kilometre = one thousand metres).

Times longer than one second are expressed in the units seconds, minutes, hours, days, weeks, and years. Times shorter than one second are expressed as decimal fractions (a millisecond = one-thousandth of a second, a microsecond = one-millionth of a second, and so on). The fundamental unit of time (*i.e.*, the definition of one second) is today based on the intrinsic properties of certain kinds of atoms (an excitation frequency of the isotope cesium-133).

Units of mass are also defined in a way that is technically sound, but in common usage they are the subject of some

confusion because they are easily confused with units of weight, which is a different physical quantity. The weight of an object is the consequence of the Earth's gravity operating on its mass. Thus, the mass of a given object is the same everywhere, but its weight varies slightly if it is moved about the surface of the Earth, and it would change a great deal if it were moved to the surface of another planet. Also, weight and mass do not have the same dimensions (weight has the dimensions ml/t^2). The Constitution of the United States, which calls on the government to establish uniform "weights and measures," is oblivious to this distinction, as are merchants the world over, who measure the weight of bread or produce but sell it in units of kilograms, the SI unit of mass. (The kilogram is equal to 1,000 grams; 1 gram is the mass of 1 cubic centimetre of water—under appropriate conditions of temperature and pressure.)

Vectors. The equations of mechanics are typically written in terms of Cartesian coordinates. At a certain time t, the position of a particle may be specified by giving its coordinates $x(t)$, $y(t)$, and $z(t)$ in a particular Cartesian frame of reference. However, a different observer of the same particle might choose a differently oriented set of mutually perpendicular axes, say, x', y', and z'. The motion of the particle is then described by the first observer in terms of the rate of change of $x(t)$, $y(t)$, and $z(t)$, while the second observer would discuss the rates of change of $x'(t)$, $y'(t)$, and $z'(t)$. That is, both observers see the same particle executing the same motion and obeying the same laws, but they describe the situation with different equations. This awkward situation may be avoided by means of a mathematical construction called a vector. Although vectors are mathematically simple and extremely useful in discussing mechanics, they were not developed in their modern form until late in the 19th century, when J. Willard Gibbs and Oliver Heaviside (of the United States and Britain, respectively) each applied vector analysis in order to help express the new laws of electromagnetism proposed by James Clerk Maxwell.

A vector is a quantity that has both magnitude and direction. It is typically represented symbolically by an arrow in the proper direction, whose length is proportional to the magnitude of the vector. Although a vector has magnitude and direction, it does not have position. A vector is not altered if it is displaced parallel to itself as long as its length is not changed.

By contrast to a vector, an ordinary quantity having magnitude but not direction is known as a scalar. In printed works vectors are often represented by boldface letters such as $\boldsymbol{A}$ or $\boldsymbol{X}$, and scalars are represented by lightface letters, A or X. The magnitude of a vector, denoted $|\boldsymbol{A}|$, is itself a scalar—*i.e.*, $|\boldsymbol{A}| = A$.

Mathematical operations of vectors

Because vectors are different from ordinary (*i.e.*, scalar) quantities, all mathematical operations involving vectors must be carefully defined. Addition, subtraction, three kinds of multiplication, and differentiation will be discussed here. There is no mathematical operation that corresponds to division by a vector.

If vector $\boldsymbol{A}$ is added to vector $\boldsymbol{B}$, the result is another vector, $\boldsymbol{C}$, written $\boldsymbol{A} + \boldsymbol{B} = \boldsymbol{C}$. The operation is performed by displacing $\boldsymbol{B}$ so that it begins where $\boldsymbol{A}$ ends, as shown in Figure 1A. $\boldsymbol{C}$ is then the vector that starts where $\boldsymbol{A}$ begins and ends where $\boldsymbol{B}$ ends.

Vector addition is defined to have the (nontrivial) property $\boldsymbol{A} + \boldsymbol{B} = \boldsymbol{B} + \boldsymbol{A}$. There do exist quantities having magnitude and direction that do not obey this requirement. An example is finite rotations in space. Two finite rotations of a body about different axes do not necessarily result in the same orientation if performed in the opposite order.

Vector subtraction is defined by $\boldsymbol{A} - \boldsymbol{B} = \boldsymbol{A} + (-\boldsymbol{B})$, where the vector $-\boldsymbol{B}$ has the same magnitude as $\boldsymbol{B}$ but the opposition direction. The idea is illustrated in Figure 1B.

A vector may be multiplied by a scalar. Thus, for example, the vector $2\boldsymbol{A}$ has the same direction as $\boldsymbol{A}$ but is twice as long. If the scalar has dimensions, the resulting vector still has the same direction as the original one, but the two cannot be compared in magnitude. For example, a particle moving with constant velocity $\boldsymbol{v}$ suffers a displacement $\boldsymbol{s}$ in time t given by $\boldsymbol{s} = \boldsymbol{v}t$. The vector $\boldsymbol{v}$ has been multiplied by the scalar t to give a new vector, $\boldsymbol{s}$, which has the same direction as $\boldsymbol{v}$ but cannot be compared to $\boldsymbol{v}$ in magnitude (a displacement of one metre is neither bigger nor smaller than a velocity of one metre per second). This is a typical example of a phenomenon that might be represented by different equations in differently oriented Cartesian coordinate systems but that has a single vector equation (for all observers not moving with respect to one another).

The dot product (also known as the scalar product, or sometimes the inner product) is an operation that combines two vectors to form a scalar. The operation is written $\boldsymbol{A} \cdot \boldsymbol{B}$. If θ is the (smaller) angle between $\boldsymbol{A}$ and $\boldsymbol{B}$, then the result of the operation is $\boldsymbol{A} \cdot \boldsymbol{B} = AB \cos \theta$. The dot product measures the extent to which two vectors are parallel. It may be thought of as multiplying the magnitude of one vector (either one) by the projection of the other upon it, as shown in Figure 1C. If the two vectors are perpendicular, the dot product is zero.

The cross product (also known as the vector product) combines two vectors to form another vector, perpendicular to the plane of the original vectors. The operation is written $\boldsymbol{A} \times \boldsymbol{B}$. If θ is the (smaller) angle between $\boldsymbol{A}$ and $\boldsymbol{B}$, then $|\boldsymbol{A} \times \boldsymbol{B}| = AB \sin \theta$. The direction of $\boldsymbol{A} \times \boldsymbol{B}$ is given

From R.P. Olenick, T.M. Apostol, and D.L. Goodstein, *The Mechanical Universe: Introduction to Mechanics and Heat* (1985), Cambridge University Press

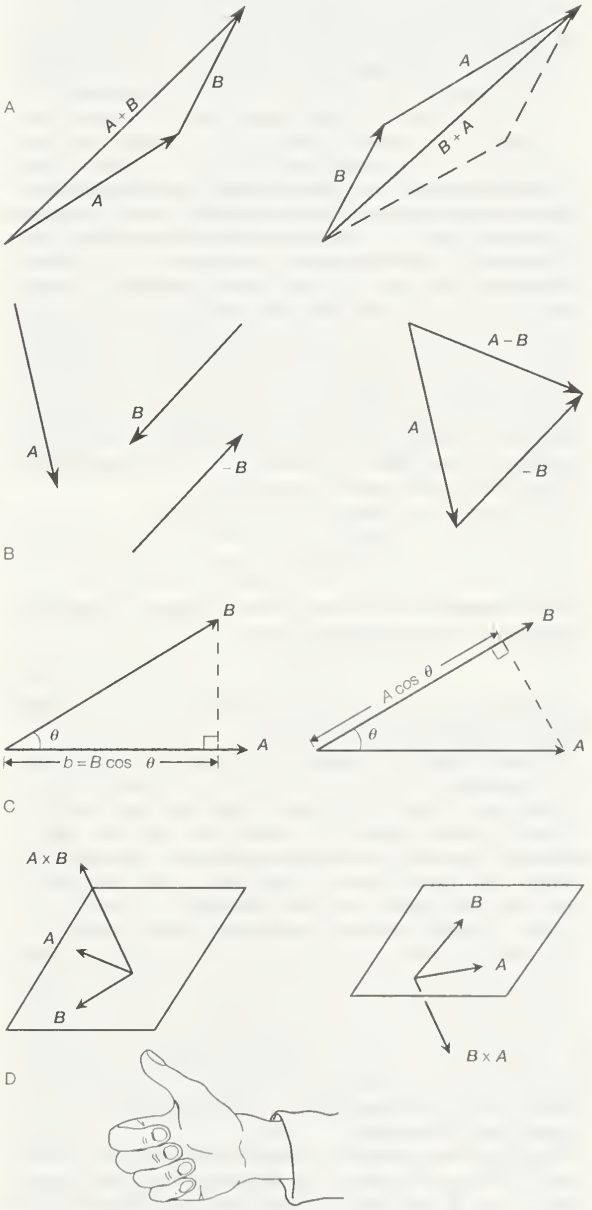

Figure 1: (A, left) The vector sum $\boldsymbol{A} + \boldsymbol{B}$ and (right) the vector sum $\boldsymbol{B} + \boldsymbol{A}$. (B, left) The vectors $\boldsymbol{A}$, $\boldsymbol{B}$, and $-\boldsymbol{B}$ and (right) the vector difference $\boldsymbol{A} - \boldsymbol{B}$. (C, left) $B \cos \theta$ is the component of $\boldsymbol{B}$ along $\boldsymbol{A}$, and (right) $A \cos \theta$ is the component of $\boldsymbol{A}$ along $\boldsymbol{B}$. (D, left) The right-hand rule used to find the direction of $\boldsymbol{A} \times \boldsymbol{B}$ and (right) the right-hand rule used to find the direction of $\boldsymbol{B} \times \boldsymbol{A}$.

Right-hand rule

by the right-hand rule: if the fingers of the right hand are made to rotate from A through θ to B, the thumb points in the direction of $A \times B$, as shown in Figure 1D. The cross product is zero if the two vectors are parallel, and it is maximum in magnitude if they are perpendicular.

The derivative, or rate of change, of a vector is defined in perfect analogy to the derivative of a scalar: if the vector A changes with time t, then

$$\frac{dA}{dt} = \lim_{\Delta t \to 0} \frac{A(t + \Delta t) - A(t)}{\Delta t}. \quad (1)$$

Before going to the limit on the right-hand side of equation (1), the operations described are vector subtraction $[A(t + \Delta t) - A(t)]$ and scalar multiplication (by $1/\Delta t$). The result, dA/dt, is therefore itself a vector. Notice that, as shown in Figure 1B, the difference between two vectors, in this case $A(t + \Delta t) - A(t)$, may be in quite a different direction than either of the vectors from which it is formed, here $A(t + \Delta t)$ and $A(t)$. As a result, dA/dt may be in a different direction than $A(t)$.

Newton's laws of motion and equilibrium. In his *Principia,* Newton reduced the basic principles of mechanics to three laws:

1. Every body continues in its state of rest or of uniform motion in a straight line, unless it is compelled to change that state by forces impressed upon it.
2. The change of motion of an object is proportional to the force impressed and is made in the direction of the straight line in which the force is impressed.
3. To every action there is always opposed an equal reaction; or, the mutual actions of two bodies upon each other are always equal and directed to contrary parts.

Newton's first law is a restatement of the principle of inertia, proposed earlier by Galileo and perfected by Descartes.

Significance of the second law of motion

The second law is the most important of the three; it may be understood very nearly to summarize all of classical mechanics. Newton used the word "motion" to mean what is today called momentum—that is, the product of mass and velocity, or $p = mv$, where p is the momentum, m the mass, and v the velocity of a body. The second law may then be written in the form of the equation $F = dp/dt$, where F is the force, the time derivative expresses Newton's "change of motion," and the vector form of the equation assures that the change is in the same direction as the force, as the second law requires.

For a body whose mass does not change,

$$\frac{dp}{dt} = m\frac{dv}{dt} = ma,$$

where a is the acceleration. Thus, Newton's second law may be put in the following form:

$$F = ma. \quad (2)$$

It is probably fair to say that equation (2) is the most famous equation in all of physics.

Newton's third law assures that when two bodies interact, regardless of the nature of the interaction, they do not produce a net force acting on the two-body system as a whole. Instead, there is an action and reaction pair of equal and opposite forces, each acting on a different body (action and reaction forces never act on the same body). The third law applies whether the bodies in question are at rest, in uniform motion, or in accelerated motion.

If a body has a net force acting on it, it undergoes accelerated motion in accordance with the second law. If there is no net force acting on a body, either because there are no forces at all or because all forces are precisely balanced by contrary forces, the body does not accelerate and may be said to be in equilibrium. Conversely, a body that is observed not to be accelerated may be deduced to have no net force acting on it.

Consider, for example, a massive object resting on a table. The object is known to be acted on by the gravitational force of the Earth; if the table were removed, the object would fall. It follows therefore from the fact that the object does not fall that the table exerts an upward force on the object, equal and opposite to the downward force of gravity. This upward force is not a mere physicist's bookkeeping device but rather a real physical force. The table's surface is slightly deformed by the weight of the object, causing the surface to exert a force analogous to that exerted by a coiled spring.

It is useful to recall the following distinction: the massive object exerts a downward force on the table that is equal and opposite to the upward force exerted by the table (owing to its deformation) on the object. These two forces are an action and reaction pair operating on different bodies (one on the table, the other on the object) as required by Newton's third law. On the other hand, the upward force exerted on the object by the table is balanced by a downward force exerted on the object by the Earth's gravity. These two equal and opposite forces, acting on the same body, are not related to or by Newton's third law, but they do produce the equilibrium immobile state of the body.

Motion of a particle in one dimension

UNIFORM MOTION

Principle of inertia

According to Newton's first law (also known as the principle of inertia), a body with no net force acting on it will either remain at rest or continue to move with uniform speed in a straight line, according to its initial condition of motion. In fact, in classical Newtonian mechanics, there is no important distinction between rest and uniform motion in a straight line; they may be regarded as the same state of motion seen by different observers, one moving at the same velocity as the particle, the other moving at constant velocity with respect to the particle.

Although the principle of inertia is the starting point and the fundamental assumption of classical mechanics, it is less than intuitively obvious to the untrained eye. In Aristotelian mechanics, and in ordinary experience, objects that are not being pushed tend to come to rest. The law of inertia was deduced by Galileo from his experiments with balls rolling down inclined planes, described above.

For Galileo, the principle of inertia was fundamental to his central scientific task: he had to explain how it is possible that if the Earth is really spinning on its axis and orbiting the Sun we do not sense that motion. The principle of inertia helps to provide the answer: Since we are in motion together with the Earth, and our natural tendency is to retain that motion, the Earth appears to us to be at rest. Thus, the principle of inertia, far from being a statement of the obvious, was once a central issue of scientific contention. By the time Newton had sorted out all the details, it was possible to account accurately for the small deviations from this picture caused by the fact that the motion of the Earth's surface is not uniform motion in a straight line (the effects of rotational motion are discussed below). In the Newtonian formulation, the common observation that bodies that are not pushed tend to come to rest is attributed to the fact that they have unbalanced forces acting on them, such as friction and air resistance.

As has already been stated, a body in motion may be said to have momentum equal to the product of its mass and its velocity. It also has a kind of energy that is due entirely to its motion, called kinetic energy. The kinetic energy of a body of mass m in motion with velocity v is given by

$$K = \frac{1}{2}mv^2. \quad (3)$$

FALLING BODIES AND UNIFORMLY ACCELERATED MOTION

During the 14th century, the French scholar Nicole Oresme studied the mathematical properties of uniformly accelerated motion. He had little interest in whether that kind of motion could be observed in the realm of actual human existence, but he did discover that, if a particle is uniformly accelerated, its speed increases in direct proportion to time, and the distance it traverses is proportional to the square of the time spent accelerating. Two centuries later, Galileo repeated these same mathematical discoveries (perhaps independently) and, just as important, determined that this kind of motion is actually executed by balls rolling down inclined planes. As the incline of the plane increases, the acceleration increases, but the

motion continues to be uniformly accelerated. From this observation, Galileo deduced that a body falling freely in the vertical direction would also have uniform acceleration. Even more remarkably, he demonstrated that, in the absence of air resistance, all bodies would fall with the same constant acceleration regardless of their mass. If the constant acceleration of any body dropped near the surface of the Earth is expressed as g, the behaviour of a body dropped from rest at height z_0 and time $t = 0$ may be summarized by the following equations:

$$z = z_0 - \frac{1}{2}gt^2, \tag{4}$$

$$v = gt, \tag{5}$$

$$a = g, \tag{6}$$

where z is the height of the body above the surface, v is its speed, and a is its acceleration. These equations of motion hold true until the body actually strikes the surface. The value of g is approximately 9.8 metres per second squared (m/s^2).

Gravitational potential energy

A body of mass m at a height z_0 above the surface may be said to possess a kind of energy purely by virtue of its position. This kind of energy (energy of position) is called potential energy. The gravitational potential energy is given by

$$U = mgz_0. \tag{7}$$

Technically, it is more correct to say that this potential energy is a property of the Earth-body system rather than a property of the body itself, but this pedantic distinction can be ignored.

As the body falls to height z less than z_0, its potential energy U converts to kinetic energy $K = \frac{1}{2}mv^2$. Thus, the speed v of the body at any height z is given by solving the equation

$$\frac{1}{2}mv^2 + mgz = mgz_0. \tag{8}$$

Equation (8) is an expression of the law of conservation of energy. It says that the sum of kinetic energy, $\frac{1}{2}mv^2$, and potential energy, mgz, at any point during the fall, is equal to the total initial energy, mgz_0, before the fall began. Exactly the same dependence of speed on height could be deduced from the kinematic equations (4), (5), and (6) above.

In order to reach the initial height z_0, the body had to be given its initial potential energy by some external agency, such as a person lifting it. The process by which a body or a system obtains mechanical energy from outside of itself is called work. The increase of the energy of the body is equal to the work done on it. Work is equal to force times distance.

The force exerted by the Earth's gravity on a body of mass m may be deduced from the observation that the body, if released, will fall with acceleration g. Since force is equal to mass times acceleration, the force of gravity is given by $F = mg$. To lift the body to height z_0, an equal and opposite (*i.e.*, upward) force must be exerted through a distance z_0. Thus, the work done is

$$W = Fz_0 = mgz_0. \tag{9}$$

which is equal to the potential energy that results.

If work is done by applying a force to a body that is not being acted upon by an opposing force, the body is accelerated. In this case, the work endows the body with kinetic energy rather than potential energy. The energy that the body gains is equal to the work done on it in either case. It should be noted that work, potential energy, and kinetic energy, all being aspects of the same quantity, must all have the dimensions ml^2/t^2.

SIMPLE HARMONIC OSCILLATIONS

Consider a mass m held in an equilibrium position by springs, as shown in Figure 2A. The mass may be perturbed by displacing it to the right or left. If x is the displacement of the mass from equilibrium (Figure 2B), the springs exert a force F proportional to x, such that

$$F = -kx, \tag{10}$$

Hooke's law

where k is a constant that depends on the stiffness of the springs. Equation (10) is called Hooke's law, and the force is called the spring force. If x is positive (displacement to the right), the resulting force is negative (to the left), and vice versa. In other words, the spring force always acts so as to restore mass back toward its equilibrium position.

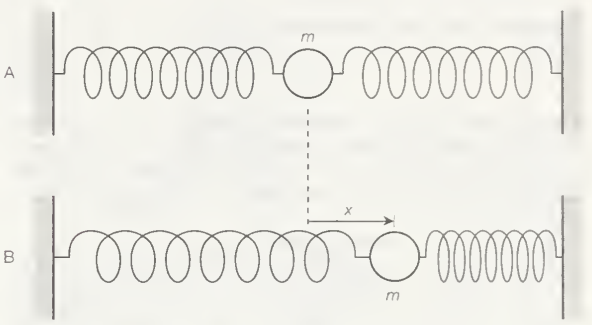

Figure 2: (A) A mass m held in equilibrium by springs. (B) A mass m displaced a distance x.

Moreover, the force will produce an acceleration along the x direction given by $a = d^2x/dt^2$. Thus, Newton's second law, $F = ma$, is applied to this case by substituting $-kx$ for F and d^2x/dt^2 for a, giving $-kx = m(d^2x/dt^2)$. Transposing and dividing by m yields the equation

$$a = \frac{d^2x}{dt^2} = -\frac{k}{m}x. \tag{11}$$

Solution of differential equations

Equation (11) gives the derivative—in this case the second derivative—of a quantity x in terms of the quantity itself. Such an equation is called a differential equation, meaning an equation containing derivatives. Much of the ordinary, day-to-day work of theoretical physics consists of solving differential equations. The question is, given equation (11), how does x depend on time?

The answer is suggested by experience. If the mass is displaced and released, it will oscillate back and forth about its equilibrium position. That is, x should be an oscillating function of t, such as a sine wave or a cosine wave. For example, x might obey a behaviour such as

$$x = A \cos \omega t. \tag{12}$$

Equation (12) describes the behaviour sketched graphically in Figure 3. The mass is initially displaced a distance $x = A$ and released at time $t = 0$. As time goes on, the mass oscillates from A to $-A$ and back to A again in the time it takes ωt to advance by 2π. This time is called T, the period of oscillation, so that $\omega T = 2\pi$, or $T = 2\pi/\omega$. The reciprocal of the period, or the frequency f, in oscillations per second, is given by $f = 1/T = \omega/2\pi$. The quantity ω is called the angular frequency and is expressed in radians per second.

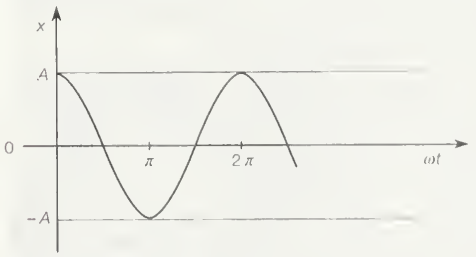

Figure 3: The function $x = A \cos \omega t$.

The choice of equation (12) as a possible kind of behaviour satisfying the differential equation (11) can be tested by substituting it into equation (11). The first derivative of x with respect to t is

$$\frac{dx}{dt} = \frac{d}{dt}(A \cos \omega t) \tag{13}$$

$$= -\omega A \sin \omega t.$$

Differentiating a second time gives

$$\frac{d^2x}{dt^2} = \frac{d}{dt}\left(\frac{dx}{dt}\right) \tag{14}$$

$$= \frac{d}{dt}(-\omega A \sin \omega t)$$

$$= -\omega^2 A \cos \omega t$$

$$= -\omega^2 x.$$

Equation (14) is the same as equation (11) if

$$\omega^2 = \frac{k}{m}. \tag{15}$$

Thus, subject to this condition, equation (12) is a correct solution to the differential equation. There are other possible correct guesses (*e.g.*, $x = A \sin \omega t$) that differ from this one only in whether the mass is at rest or in motion at the instant $t = 0$.

The mass, as has been shown, oscillates from A to $-A$ and back again. The speed, given by dx/dt, equation (13), is zero at A and $-A$, but has its maximum magnitude, equal to ωA, when x is equal to zero. Physically, after the mass is displaced from equilibrium a distance A to the right, the restoring force F pushes the mass back toward its equilibrium position, causing it to accelerate to the left. When it reaches equilibrium, there is no force acting on it at that instant, but it is moving at speed ωA, and its inertia takes it past the equilibrium position. Before it is stopped it reaches position $-A$, and by this time there is a force acting on it again, pushing it back toward equilibrium.

Frequency of simple harmonic motion

The whole process, known as simple harmonic motion, repeats itself endlessly with a frequency given by equation (15). Equation (15) means that the stiffer the springs (*i.e.*, the larger k), the higher the frequency (the faster the oscillations). Making the mass greater has exactly the opposite effect, slowing things down.

One of the most important features of harmonic motion is the fact that the frequency of the motion, ω (or f), depends only on the mass and the stiffness of the spring. It does not depend on the amplitude A of the motion. If the amplitude is increased, the mass moves faster, but the time required for a complete round trip remains the same. This fact has profound consequences, governing the nature of music and the principle of accurate timekeeping.

The potential energy of a harmonic oscillator, equal to the work an outside agent must do to push the mass from zero to x, is $U = \frac{1}{2}kx^2$. Thus, the total initial energy in the situation described above is $\frac{1}{2}kA^2$; and since the kinetic energy is always $\frac{1}{2}mv^2$, when the mass is at any point x in the oscillation,

$$\frac{1}{2}mv^2 + \frac{1}{2}kx^2 = \frac{1}{2}kA^2. \tag{16}$$

Equation (16) plays exactly the role for harmonic oscillators that equation (8) does for falling bodies.

It is quite generally true that harmonic oscillations result from disturbing any body or structure from a state of stable mechanical equilibrium. To understand this point, a brief discussion of stability is useful.

Mechanical equilibrium

Consider a bowl with a marble resting inside, then consider a second, inverted bowl with a marble balanced on top. In both cases, the net force on the marble is zero. The marbles are thus in mechanical equilibrium. However, a small disturbance in the position of the marble balanced on top of the inverted bowl will cause it to roll away and not return. In such a case, the equilibrium is said to be unstable. Conversely, if the marble inside the first bowl is disturbed, gravity acts to push it back toward the bottom of the bowl. The marble inside the bowl (like the mass held by springs in Figure 2A) is an example of a body in stable equilibrium. If it is disturbed slightly, it executes harmonic oscillations around the bottom of the bowl rather than rolling away.

This argument may be generalized by a simple mathematical argument. Consider a body or structure in mechanical equilibrium, which, when disturbed by a small amount x, finds a force acting on it that is a function of x, $F(x)$. For small x, such a function may be written generally as a power series in x; *i.e.*,

$$F(x) = F(0) + ax + bx^2 + \cdots, \tag{17}$$

where $F(0)$ is the value of $F(x)$ when $x = (0)$, and a and b are constants, independent of x, determined by the nature of the system. The statement that the body is in mechanical equilibrium means that $F(0) = 0$, so that no force is acting on the body when it is undisturbed. Since x is small, x^2 is much smaller; thus the term bx^2 and all higher powers may be disregarded. This leaves $F(x) = ax$. Now, if a is positive, a disturbance produces a force in the same direction as the disturbance. This was the case when the marble was balanced on top of the inverted bowl. It describes unstable equilibrium. For the system to be stable, a must be negative. Thus, if $a = -k$, where k is some positive constant, equation (17) becomes $F(x) = -kx$, which is simply Hooke's law, equation (10). As has been described above, any system obeying Hooke's law is a harmonic oscillator.

The generality of this argument accounts for the fact that harmonic oscillators are abundantly observed in common experience. For example, any rigid structure will oscillate at many different harmonic frequencies corresponding to different possible distortions of its equilibrium shape. In addition, music may be produced either by disturbing the equilibrium of a stretched wire or fibre (as in the piano and violin), a stretched membrane (*e.g.*, drums), or a rigid bar (the triangle and the xylophone) or by disturbing the density of an enclosed column of air (as in the trumpet and organ). While a fluid such as air is not rigid, its density is an example of a stable system that obeys Hooke's law and may therefore be set into harmonic oscillations.

All music would be quite different from what it is were it not for the general property of harmonic oscillators that the frequency is independent of the amplitude. Thus, instruments yield the same note (frequency) regardless of how loudly they are played (amplitude), and, equally important, the same note persists as the vibrations die away. This same property of harmonic oscillators is the underlying principle of all accurate timekeeping.

Harmonic oscillators as timekeepers

The first precise timekeeping mechanism, whose principles of motion were discovered by Galileo, was the simple pendulum (see below). The accuracy of modern timekeeping has been improved dramatically by the introduction of tiny quartz crystals, whose harmonic oscillations generate electrical signals that may be incorporated into miniaturized circuits in clocks and wristwatches. All harmonic oscillators are natural timekeeping devices because they oscillate at intrinsic natural frequencies independent of amplitude. A given number of complete cycles always corresponds to the same elapsed time. Quartz crystal oscillators make more accurate clocks than pendulums do principally because they oscillate many more times per second.

DAMPED AND FORCED OSCILLATIONS

The simple harmonic oscillations discussed above continue forever, at constant amplitude, oscillating as shown in Figure 3 between A and $-A$. Common experience indicates that real oscillators behave somewhat differently, however. Harmonic oscillations tend to die away as time goes on. This behaviour, called damping of the oscillations, is produced by forces such as friction and viscosity. These forces are known collectively as dissipative forces because they tend to dissipate the potential and kinetic energies of macroscopic bodies into the energy of the chaotic motion of atoms and molecules known as heat.

Friction and viscosity are complicated phenomena whose effects cannot be represented accurately by a general equation. However, for slowly moving bodies, the dissipative forces may be represented by

$$F_d = -\gamma v, \tag{18}$$

where v is the speed of the body and γ is a constant coefficient, independent of dynamic quantities such as speed or displacement. Equation (18) is most easily understood by an argument analogous to that applied to equation (17) above. F_d is written as a sum of powers of v, or $F_d(v) = F_d(0) + av + bv^2 + \cdots$. When the body is at rest ($v = 0$), no dissipative force is expected because, if

there were one, it might set the body into motion. Thus, $F_d(0) = 0$. The next term must be negative since dissipative forces always resist the motion. Thus, $a = -\gamma$ where γ is positive. Since v^2 has the same sign regardless of the direction of the motion, b must equal 0 lest it sometimes contribute a dissipative force in the same direction as the motion. The next term is proportional to v^3, and it and all subsequent terms may be neglected if v is sufficiently small. So, as in equation (17) the power series is reduced to a single term, in this case $F_d = -\gamma v$.

To find the effect of a dissipative force on a harmonic oscillator, a new differential equation must be solved. The net force, or mass times acceleration, written as md^2x/dt^2, is set equal to the sum of the Hooke's law force, $-kx$, and the dissipative force, $-\gamma v = -\gamma dx/dt$. Dividing by m yields

$$\frac{d^2x}{dt^2} = -\frac{k}{m}x - \frac{\gamma}{m}\frac{dx}{dt}. \tag{19}$$

The general solution to equation (19) is given in the form $x = Ce^{-\gamma t/2m}\cos(\omega t + \theta_0)$, where C and θ_0 are arbitrary constants determined by the initial conditions. This motion, for the case in which $\theta_0 = 0$, is illustrated in Figure 4. As expected, the harmonic oscillations die out with time. The amplitude of the oscillations is bounded by an exponentially decreasing function of time (the dashed curves). The characteristic decay time (after which the oscillations are smaller by $1/e$, where e is the base of the natural logarithms $e = 2.718\ldots$) is equal to $2m/\gamma$. The frequency of the oscillations is given by

$$\omega^2 = \frac{k}{m} - \frac{\gamma^2}{4m^2}. \tag{20}$$

Importantly, this frequency does not change as the oscillations decay.

From S.C. Frautschi *et al.*, *The Mechanical Universe: Mechanics and Heat, Advanced Edition* (1986), Cambridge University Press

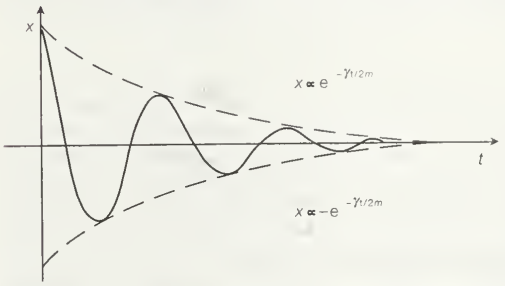

Figure 4: Damped oscillations.

Equation (20) shows that it is possible, by proper choice of γ, to turn a harmonic oscillator into a system that does not oscillate at all—that is, a system whose natural frequency is $\omega = 0$. Such a system is said to be critically damped. For example, the springs that suspend the body of an automobile cause it to be a natural harmonic oscillator. The shock absorbers of the auto are devices that seek to add just enough dissipative force to make the assembly critically damped. In this way, the passengers need not go through numerous oscillations after each bump in the road.

Resonance

A simple disturbance can set a harmonic oscillator into motion. Repeated disturbances can increase the amplitude of the oscillations if they are applied in synchrony with the natural frequency. Even a very small disturbance, repeated periodically at just the right frequency, can cause a very large amplitude motion to build up. This phenomenon is known as resonance.

Periodically forced oscillations may be represented mathematically by adding a term of the form $a_0 \sin \omega t$ to the right-hand side of equation (19). This term describes a force applied at frequency ω, with amplitude ma_0. The result of applying such a force is to create a kind of motion that does not need to decay with time, since the energy lost to dissipative processes is replaced, over the course of each cycle, by the driving force. The amplitude of the motion depends on how close the driving frequency ω is to the natural frequency ω_0 of the oscillator. Interestingly, even though dissipation is present, ω_0 is not given by

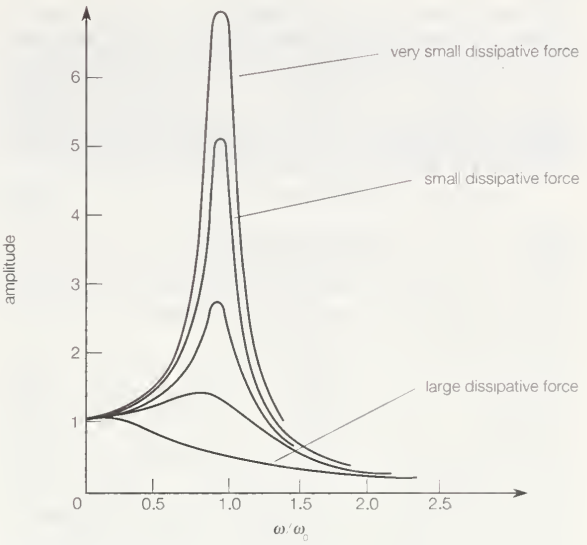

Figure 5: Resonance curves for different amounts of dissipative force acting on an oscillator.

From S.C. Frautschi *et al.*, *The Mechanical Universe: Mechanics and Heat, Advanced Edition* (1986), Cambridge University Press

equation (20) but rather by equation (15): $\omega_0^2 = k/m$. The amplitude of the steady state motion (*i.e.*, long after the driving force has begun to be applied) is shown in Figure 5. The maximum amplitude occurs as expected at $\omega = \omega_0$. The height and width of the resonance curve are governed by the damping coefficient γ. If there were no damping, the maximum amplitude would be infinite. Because small disturbances at every possible frequency are always present in the natural world, every rigid structure would shake itself to pieces if not for the presence of internal damping.

Resonances are not uncommon in the world of familiar experience. For example, cars often rattle at certain engine speeds, and windows sometimes rattle when an airplane flies by. Resonance is particularly important in music. For example, the sound box of a violin does its job well if it has a natural frequency of oscillation that responds resonantly to each musical note. Very strong resonances to certain notes—called "wolf notes" by musicians—occur in cheap violins and are much to be avoided. Sometimes, a glass may be broken by a singer as a result of its resonant response to a particular musical note.

Motion of a particle in two or more dimensions

PROJECTILE MOTION

Galileo was quoted above pointing out with some detectable pride that none before him had realized that the curved path followed by a missile or projectile is a parabola. He had arrived at his conclusion by realizing that a body undergoing ballistic motion executes, quite independently, the motion of a freely falling body in the vertical direction and inertial motion in the horizontal direction. These considerations, and terms such as ballistic and projectile, apply to a body that, once launched, is acted upon by no force other than the Earth's gravity.

Three-dimensional motion

Projectile motion may be thought of as an example of motion in space—that is to say, of three-dimensional motion rather than motion along a line, or one-dimensional motion. In a suitably defined system of Cartesian coordinates, the position of the projectile at any instant may be specified by giving the values of its three coordinates, $x(t)$, $y(t)$, and $z(t)$. By generally accepted convention, $z(t)$ is used to describe the vertical direction. To a very good approximation, the motion is confined to a single vertical plane, so that for any single projectile it is possible to choose a coordinate system such that the motion is two-dimensional [say, $x(t)$ and $z(t)$] rather than three-dimensional [$x(t)$, $y(t)$, and $z(t)$]. It is assumed throughout this section that the range of the motion is sufficiently limited that the curvature of the Earth's surface may be ignored.

Consider a body whose vertical motion obeys equation (4), Galileo's law of falling bodies, which states $z = z_0 - \frac{1}{2}gt^2$, while, at the same time, moving horizontally at

a constant speed v_x in accordance with Galileo's law of inertia. The body's horizontal motion is thus described by $x(t) = v_x t$, which may be written in the form $t = x/v_x$. Using this result to eliminate t from equation (4) gives $z = z_0 - \frac{1}{2}g(1/v_x)^2x^2$. This latter is the equation of the trajectory of a projectile in the z–x plane, fired horizontally from an initial height z_0. It has the general form

$$z = a + bx^2, \tag{21}$$

where a and b are constants. Equation (21) may be recognized to describe a parabola (Figure 6A), just as Galileo claimed. The parabolic shape of the trajectory is preserved even if the motion has an initial component of velocity in the vertical direction (Figure 6B).

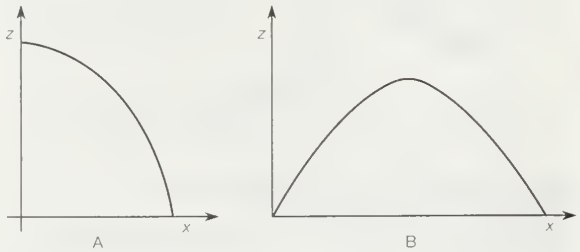

Figure 6: (A) The parabolic path of a projectile. (B) The parabolic path of a projectile with an initial upward component of velocity.

Energy is conserved in projectile motion. The potential energy $U(z)$ of the projectile is given by $U(z) = mgz$. The kinetic energy K is given by $K = \frac{1}{2}mv^2$, where v^2 is equal to the sum of the squares of the vertical and horizontal components of velocity, or $v^2 = v_x^2 + v_z^2$.

Effects of air resistance

In all of this discussion, the effects of air resistance (to say nothing of wind and other more complicated phenomena) have been neglected. These effects are seldom actually negligible. They are most nearly so for bodies that are heavy and slow-moving. All of this discussion, therefore, is of great value for understanding the underlying principles of projectile motion but of little utility for predicting the actual trajectory of, say, a cannonball once fired or even a well-hit baseball.

MOTION OF A PENDULUM

Galileo's discovery of pendulum motion

According to legend, Galileo discovered the principle of the pendulum while attending mass at the Duomo (cathedral) located in the Piazza del Duomo of Pisa, Italy. A lamp hung from the ceiling by a cable and, having just been lit, was swaying back and forth. Galileo realized that each complete cycle of the lamp took the same amount of time, compared to his own pulse, even though the amplitude of each swing was smaller than the last. As has already been shown, this property is common to all harmonic oscillators, and, indeed, Galileo's discovery led directly to the invention of the first accurate mechanical clocks. Galileo was also able to show that the period of oscillation of a simple pendulum is proportional to the square root of its length and does not depend on its mass.

A simple pendulum is sketched in Figure 7. A bob of mass M is suspended by a massless cable or bar of length L from a point about which it pivots freely. The angle between the cable and the vertical is called θ. The force

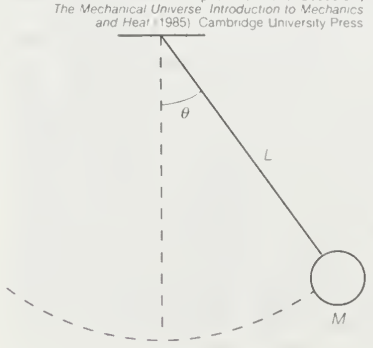

Figure 7: A simple pendulum (see text).

of gravity acting on the mass M, always equal to $-Mg$ in the vertical direction, is a vector that may be resolved into two components, one that acts ineffectually along the cable and another, perpendicular to the cable, that tends to restore the bob to its equilibrium position directly below the point of suspension. This latter component is given by

$$F = -Mg \sin \theta. \tag{22}$$

The bob is constrained by the cable to swing through an arc that is actually a segment of a circle of radius L. If the cable is displaced through an angle θ, the bob moves a distance $L\theta$ along its arc (θ must be expressed in radians for this form to be correct). Thus, Newton's second law may be written

$$F = Ma = M\frac{d^2(L\theta)}{dt^2}. \tag{23}$$

Equating equation (22) to equation (23), one sees immediately that the mass M will drop out of the resulting equation. The simple pendulum is an example of a falling body, and its dynamics do not depend on its mass for exactly the same reason that the acceleration of a falling body does not depend on its mass: both the force of gravity and the inertia of the body are proportional to the same mass, and the effects cancel one another. The equation that results (after extracting the constant L from the derivative and dividing both sides by L) is

$$\frac{d^2\theta}{dt^2} = -\frac{g}{L}\sin \theta. \tag{24}$$

If the angle θ is sufficiently small, equation (24) may be rewritten in a form that is both more familiar and more amenable to solution. Figure 8 shows a segment of a circle of radius L. A radius vector at angle θ, as shown, locates a point on the circle displaced a distance $L\theta$ along the arc.

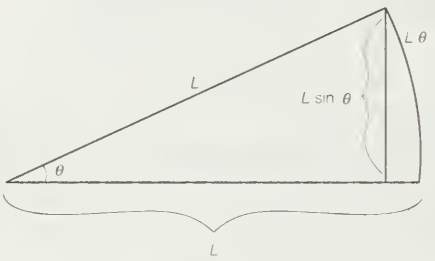

Figure 8: A segment of a circle of radius L (see text).

It is clear from the geometry that $L \sin \theta$ and $L\theta$ are very nearly equal for small θ. It follows then that $\sin \theta$ and θ are also very nearly equal for small θ. Thus, if the analysis is restricted to small angles, then $\sin \theta$ may be replaced by θ in equation (24) to obtain

$$\frac{d^2\theta}{dt^2} = -\frac{g}{L}\theta. \tag{25}$$

Equation (25) should be compared with equation (11): $d^2x/dt^2 = -(k/m)x$. In the first case, the dynamic variable (meaning the quantity that changes with time) is θ, in the second case it is x. In both cases, the second derivative of the dynamic variable with respect to time is equal to the variable itself multiplied by a negative constant. The equations are therefore mathematically identical and have the same solution—*i.e.*, equation (12), or $\theta = A \cos \omega t$. In the case of the pendulum, the frequency of the oscillations is given by the constant in equation (25), or $\omega^2 = g/L$. The period of oscillation, $T = 2\pi/\omega$, is therefore

Period of oscillation

$$T = 2\pi\sqrt{\frac{L}{g}}.$$

Just as Galileo concluded, the period is independent of the mass and proportional to the square root of the length.

As with most problems in physics, this discussion of the pendulum has involved a number of simplifications and approximations. Most obviously, $\sin \theta$ was replaced by θ to obtain equation (25). This approximation is surprisingly accurate. For example, at a not-very-small angle of 17.2°, corresponding to 0.300 radian, $\sin \theta$ is equal to 0.296, an

error of less than 2 percent. For smaller angles, of course, the error is appreciably smaller.

The problem was also treated as if all the mass of the pendulum were concentrated at a point at the end of the cable. This approximation assumes that the mass of the bob at the end of the cable is much larger than that of the cable and that the physical size of the bob is small compared with the length of the cable. When these approximations are not sufficient, one must take into account the way in which mass is distributed in the cable and bob. This is called the physical pendulum, as opposed to the idealized model of the simple pendulum. Significantly, the period of a physical pendulum does not depend on its total mass either.

The effects of friction, air resistance, and the like have also been ignored. These dissipative forces have the same effects on the pendulum as they do on any other kind of harmonic oscillator, as discussed above. They cause the amplitude of a freely swinging pendulum to grow smaller on successive swings. Conversely, in order to keep a pendulum clock going, a mechanism is needed to restore the energy lost to dissipative forces.

CIRCULAR MOTION

Consider a particle moving along the perimeter of a circle at a uniform rate, such that it makes one complete revolution every hour. To describe the motion mathematically, a vector is constructed from the centre of the circle to the particle. The vector then makes one complete revolution every hour. In other words, the vector behaves exactly like the large hand on a wristwatch, an arrow of fixed length that makes one complete revolution every hour. The motion of the point of the vector is an example of uniform circular motion, and the period T of the motion is equal to one hour ($T = 1$ h). The arrow sweeps out an angle of 2π radians (one complete circle) per hour. This rate is called the angular frequency and is written $\omega = 2\pi$ h^{-1}. Quite generally, for uniform circular motion at any rate,

Angular frequency

$$T = \frac{2\pi}{\omega}. \tag{26}$$

These definitions and relations are the same as they are for harmonic motion, discussed above.

Consider a coordinate system, as shown in Figure 9A, with the circle centred at the origin. At any instant of time, the position of the particle may be specified by giving the radius r of the circle and the angle θ between the position vector and the x-axis. Although r is constant, θ increases uniformly with time t, such that $\theta = \omega t$, or $d\theta/dt = \omega$, where ω is the angular frequency in equation (26). Contrary to the case of the wristwatch, however, ω is positive by convention when the rotation is in the counterclockwise sense. The vector r has x and y components given by

$$x = r\cos\theta = r\cos\omega t, \tag{27}$$

$$y = r\sin\theta = r\sin\omega t. \tag{28}$$

One meaning of equations (27) and (28) is that, when a particle undergoes uniform circular motion, its x and y components each undergo simple harmonic motion. They are, however, not in phase with one another: at the instant when x has its maximum amplitude (say, at $\theta = 0$), y has zero amplitude, and vice versa.

In a short time, Δt, the particle moves $r\Delta\theta$ along the circumference of the circle, as shown in Figure 9B. The average speed of the particle is thus given by

$$\bar{v} = r\frac{\Delta\theta}{\Delta t}. \tag{29}$$

Average particle velocity

The average velocity of the particle is a vector given by

$$\bar{\boldsymbol{v}} = \frac{\boldsymbol{r}(t+\Delta t) - \boldsymbol{r}(t)}{\Delta t}. \tag{30}$$

This operation of vector subtraction is indicated in Figure 9B. It yields a vector that is nearly perpendicular to $\boldsymbol{r}(t)$ and $\boldsymbol{r}(t+\Delta t)$. Indeed, the instantaneous velocity, found by allowing Δt to shrink to zero, is a vector $\boldsymbol{v}$ that is perpendicular to $\boldsymbol{r}$ at every instant and whose magnitude is

$$|\boldsymbol{v}| = r\frac{d\theta}{dt} = r\omega. \tag{31}$$

The relationship between $\boldsymbol{r}$ and $\boldsymbol{v}$ is shown in Figure 9C. It means that the particle's instantaneous velocity is always tangent to the circle.

Notice that, just as the position vector $\boldsymbol{r}$ may be described in terms of the components x and y given by equations (27) and (28), the velocity vector $\boldsymbol{v}$ may be described in terms of its projections on the x and y axes, given by

$$v_x = \frac{dx}{dt} = -r\omega\sin\omega t, \tag{32}$$

$$v_y = \frac{dy}{dt} = r\omega\cos\omega t. \tag{33}$$

Imagine a new coordinate system, in which a vector of length ωr extends from the origin and points at all times in the same direction as $\boldsymbol{v}$. This construction is shown in Figure 9D. Each time the particle sweeps out a complete circle, this vector also sweeps out a complete circle. In fact, its point is executing uniform circular motion at the same angular frequency as the particle itself. Because vectors have magnitude and direction, but not position in space, the vector that has been constructed is the velocity $\boldsymbol{v}$. The velocity of the particle is itself undergoing uniform circular motion at angular frequency ω.

Although the speed of the particle is constant, the parti-

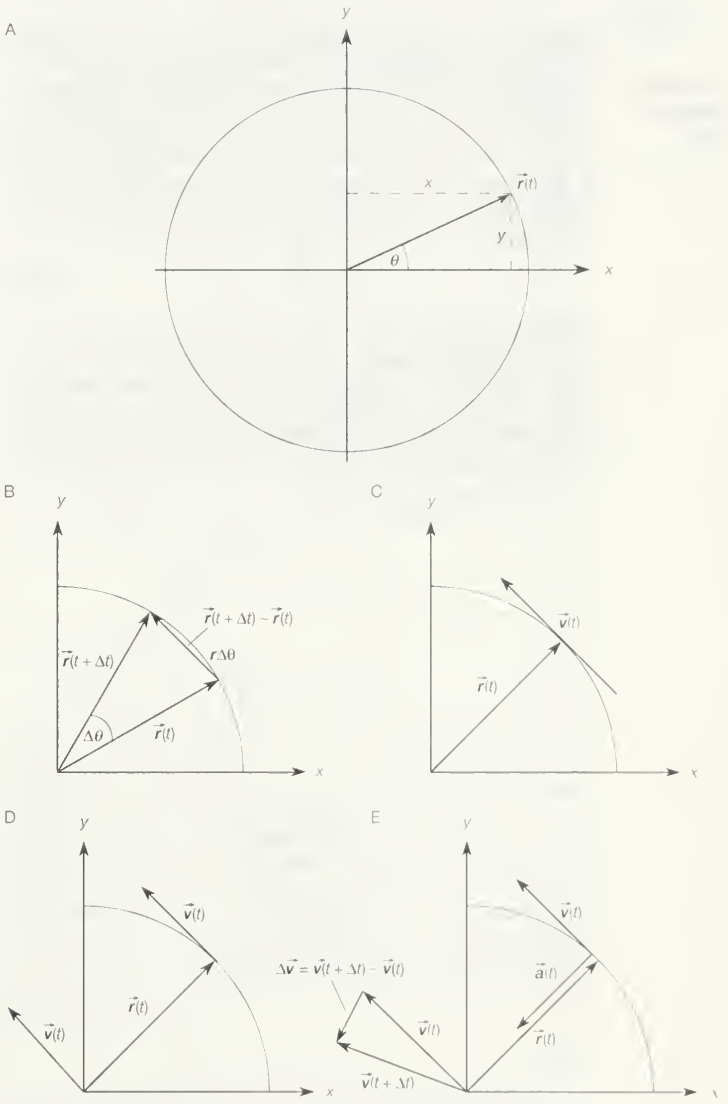

Figure 9: (A) A coordinate system to describe uniform circular motion. (B) The distance traveled in time Δt by a particle undergoing uniform circular motion. (C) The instantaneous velocity of the particle. (D) The velocity vector v undergoes uniform circular motion at the same angular frequency as the particle. (E) The acceleration vector of the particle. (See text.)

cle is nevertheless accelerated, because its velocity is constantly changing direction. The acceleration $\boldsymbol{a}$ is given by

$$\boldsymbol{a} = \frac{d\boldsymbol{v}}{dt}. \tag{34}$$

Since $\boldsymbol{v}$ is a vector of length $r\omega$ undergoing uniform circular motion, equations (29) and (30) may be repeated, as illustrated in Figure 9E, giving

$$\bar{a} = r\omega\frac{\Delta\theta}{\Delta t} \tag{35}$$

$$\bar{\boldsymbol{a}} = \frac{\boldsymbol{v}(t+\Delta t) - \boldsymbol{v}(t)}{\Delta t}. \tag{36}$$

Thus, one may conclude that the instantaneous acceleration is always perpendicular to $\boldsymbol{v}$ and its magnitude is

$$|\boldsymbol{a}| = r\omega\frac{d\theta}{dt} = r\omega^2. \tag{37}$$

Since $\boldsymbol{v}$ is perpendicular to $\boldsymbol{r}$, and $\boldsymbol{a}$ is perpendicular to $\boldsymbol{v}$, the vector $\boldsymbol{a}$ is rotated 180° with respect to $\boldsymbol{r}$. In other words, the acceleration is parallel to $\boldsymbol{r}$ but in the opposite direction. The same conclusion may be reached by realizing that $\boldsymbol{a}$ has x and y components given by

$$a_x = \frac{dv_x}{dt} = -r\omega^2 \cos \omega t, \tag{38}$$

$$a_y = \frac{dv_y}{dt} = -r\omega^2 \sin \omega t, \tag{39}$$

similar to equations (32) and (33). When equations (38) and (39) are compared with equations (27) and (28) for x and y, it is clear that the components of $\boldsymbol{a}$ are just those of $\boldsymbol{r}$ multiplied by $-\omega^2$, so that $\boldsymbol{a} = -\omega^2\boldsymbol{r}$. This acceleration is called the centripetal acceleration, meaning that it is inward, pointing along the radius vector toward the centre of the circle. It is sometimes useful to express the centripetal acceleration in terms of the speed v. Using $v = \omega r$, one can write

Centripetal acceleration

$$a = -\frac{v^2}{r}. \tag{40}$$

CIRCULAR ORBITS

The detailed behaviour of real orbits is the concern of celestial mechanics (see below). This section treats only the idealized, uniform circular orbit of a planet such as the Earth about a central body such as the Sun. In fact, the Earth's orbit about the Sun is not quite exactly uniformly circular, but it is a close enough approximation for the purposes of this discussion.

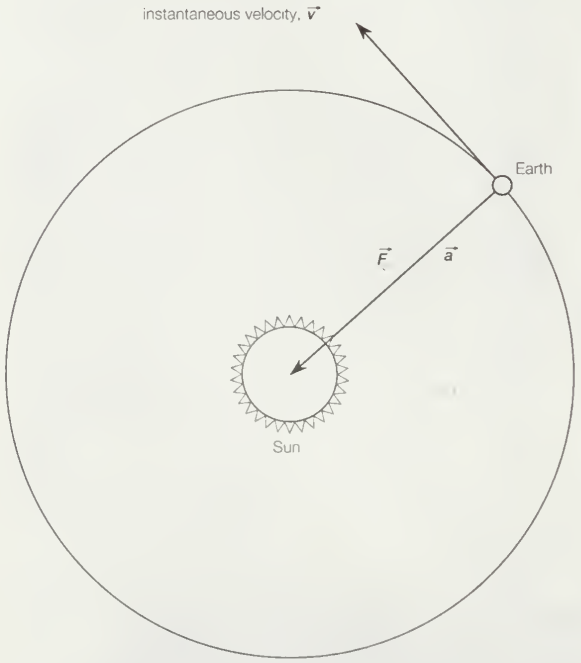

Figure 10: The gravitational force $\boldsymbol{F}_G$ exerted by the Sun on the Earth produces the centripetal acceleration $\boldsymbol{a}_c$ of the Earth's orbital motion.

A body in uniform circular motion undergoes at all times a centripetal acceleration given by equation (40). According to Newton's second law, a force is required to produce this acceleration. In the case of an orbiting planet, the force is gravity. The situation is illustrated in Figure 10. The gravitational attraction of the Sun is an inward (centripetal) force acting on the Earth. This force produces the centripetal acceleration of the orbital motion.

Before these ideas are expressed quantitatively, an understanding of why a force is needed to maintain a body in an orbit of constant speed is useful. The reason is that, at each instant, the velocity of the planet is tangent to the orbit. In the absence of gravity, the planet would obey the law of inertia (Newton's first law) and fly off in a straight line in the direction of the velocity at constant speed. The force of gravity serves to overcome the inertial tendency of the planet, thereby keeping it in orbit.

The gravitational force between two bodies such as the Sun and the Earth is given by

$$F = -G\frac{M_S M_E}{r^2}, \tag{41}$$

where M_S and M_E are the masses of the Sun and the Earth, respectively, r is the distance between their centres, and G is a universal constant equal to 6.672×10^{-11} Nm^2/kg^2 (Newton metres squared per kilogram squared). The force acts along the direction connecting the two bodies (*i.e.*, along the radius vector of the uniform circular motion), and the minus sign signifies that the force is attractive, acting to pull the Earth toward the Sun.

To an observer on the surface of the Earth, the planet appears to be at rest at (approximately) a constant distance from the Sun. It would appear to the observer, therefore, that any force (such as the Sun's gravity) acting on the Earth must be balanced by an equal and opposite force that keeps the Earth in equilibrium. In other words, if gravity is trying to pull the Earth into the Sun, some opposing force must be present to prevent that from happening. In reality, no such force exists. The Earth is in freely accelerated motion caused by an unbalanced force. The apparent force, known in mechanics as a pseudoforce, is due to the fact that the observer is actually in accelerated motion. In the case of orbital motion, the outward pseudoforce that balances gravity is called the centrifugal force.

Pseudoforce

For a uniform circular orbit, gravity produces an inward acceleration given by equation (40), $a = -v^2/r$. The pseudoforce f needed to balance this acceleration is just equal to the mass of the Earth times an equal and opposite acceleration, or $f = M_E v^2/r$. The earthbound observer then believes that there is no net force acting on the planet—*i.e.*, that $F + f = 0$, where F is the force of gravity given by equation (41). Combining these equations yields a relation between the speed v of a planet and its distance r from the Sun:

$$v^2 = G\frac{M_S}{r}. \tag{42}$$

It should be noted that the speed does not depend on the mass of the planet. This occurs for exactly the same reason that all bodies fall toward Earth with the same acceleration and that the period of a pendulum is independent of its mass. An orbiting planet is in fact a freely falling body.

Equation (42) is a special case (for circular orbits) of Kepler's third law, which will be encountered below in *Celestial mechanics*. Using the fact that $v = 2\pi r/T$, where $2\pi r$ is the circumference of the orbit and T is the time to make a complete orbit (*i.e.*, T is one year in the life of the planet), it is easy to show that $T^2 = (4\pi^2/GM_S)r^3$. This relation also may be applied to satellites in circular orbit around the Earth (in which case, M_E must be substituted for M_S) or in orbit around any other central body.

ANGULAR MOMENTUM AND TORQUE

A particle of mass m and velocity $\boldsymbol{v}$ has linear momentum $\boldsymbol{p} = m\boldsymbol{v}$. The particle may also have angular momentum $\boldsymbol{L}$ with respect to a given point in space. If $\boldsymbol{r}$ is the vector from the point to the particle, then

$$\boldsymbol{L} = \boldsymbol{r} \times \boldsymbol{p}. \tag{43}$$

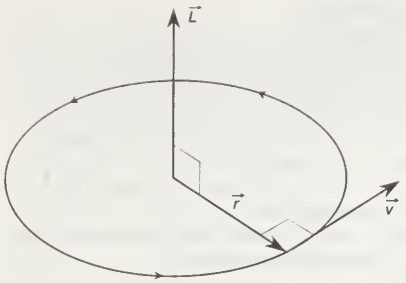

Figure 11: The angular momentum $\boldsymbol{L}$ of a particle traveling in a circular orbit.

From R.P. Olenick, T.M. Apostol, and D.L. Goodstein, *The Mechanical Universe: Introduction to Mechanics and Heat* (1985). Cambridge University Press

Notice that angular momentum is always a vector perpendicular to the plane defined by the vectors $\boldsymbol{r}$ and $\boldsymbol{p}$ (or $\boldsymbol{v}$). For example, if the particle (or a planet) is in a circular orbit, its angular momentum with respect to the centre of the circle is perpendicular to the plane of the orbit and in the direction given by the vector cross product right-hand rule, as shown in Figure 11. Moreover, since in the case of a circular orbit, $\boldsymbol{r}$ is perpendicular to $\boldsymbol{p}$ (or $\boldsymbol{v}$), the magnitude of $\boldsymbol{L}$ is simply

$$L = rp = mvr. \tag{44}$$

The significance of angular momentum arises from its derivative with respect to time,

$$\frac{d\boldsymbol{L}}{dt} = \frac{d}{dt}(\boldsymbol{r}\times\boldsymbol{p}) = m\frac{d}{dt}(\boldsymbol{r}\times\boldsymbol{v}), \tag{45}$$

where $\boldsymbol{p}$ has been replaced by $m\boldsymbol{v}$ and the constant m has been factored out. Using the product rule of differential calculus,

$$\frac{d}{dt}(\boldsymbol{r}\times\boldsymbol{v}) = \frac{d\boldsymbol{r}}{dt}\times\boldsymbol{v} + \boldsymbol{r}\times\frac{d\boldsymbol{v}}{dt}. \tag{46}$$

In the first term on the right-hand side of equation (46), $d\boldsymbol{r}/dt$ is simply the velocity $\boldsymbol{v}$, leaving $\boldsymbol{v}\times\boldsymbol{v}$. Since the cross product of any vector with itself is always zero, that term drops out, leaving

$$\frac{d}{dt}(\boldsymbol{r}\times\boldsymbol{v}) = \boldsymbol{r}\times\frac{d\boldsymbol{v}}{dt}. \tag{47}$$

Here, $d\boldsymbol{v}/dt$ is the acceleration $\boldsymbol{a}$ of the particle. Thus, if equation (47) is multiplied by m, the left-hand side becomes $d\boldsymbol{L}/dt$, as in equation (45), and the right-hand side may be written $\boldsymbol{r}\times m\boldsymbol{a}$. Since, according to Newton's second law, $m\boldsymbol{a}$ is equal to $\boldsymbol{F}$, the net force acting on the particle, the result is

$$\frac{d\boldsymbol{L}}{dt} = \boldsymbol{r}\times\boldsymbol{F}. \tag{48}$$

Equation (48) means that any change in the angular momentum of a particle must be produced by a force that is not acting along the same direction as $\boldsymbol{r}$. One particularly important application is the solar system. Each planet is held in its orbit by its gravitational attraction to the Sun, a force that acts along the vector from the Sun to the planet. Thus the force of gravity cannot change the angular momentum of any planet with respect to the Sun. Therefore, each planet has constant angular momentum with respect to the Sun. This conclusion is correct even though the real orbits of the planets are not circles but ellipses.

Torque

The quantity $\boldsymbol{r}\times\boldsymbol{F}$ is called the torque $\boldsymbol{\tau}$. Torque may be thought of as a kind of twisting force, the kind needed to tighten a bolt or to set a body into rotation. Using this definition, equation (48) may be rewritten

$$\boldsymbol{\tau} = \boldsymbol{r}\times\boldsymbol{F} = \frac{d\boldsymbol{L}}{dt}. \tag{49}$$

Equation (49) means that if there is no torque acting on a particle, its angular momentum is constant, or conserved. Suppose, however, that some agent applies a force $\boldsymbol{F}_a$ to the particle resulting in a torque equal to $\boldsymbol{r}\times\boldsymbol{F}_a$. According to Newton's third law, the particle must apply a force $-\boldsymbol{F}_a$ to the agent. Thus there is a torque equal to $-\boldsymbol{r}\times\boldsymbol{F}_a$ acting on the agent. The torque on the particle causes its angular momentum to change at a rate given by $d\boldsymbol{L}/dt = \boldsymbol{r}\times\boldsymbol{F}_a$. However, the angular momentum $\boldsymbol{L}_a$ of the agent is changing at the rate $d\boldsymbol{L}_a/dt = -\boldsymbol{r}\times\boldsymbol{F}_a$. Therefore, $d\boldsymbol{L}/dt + d\boldsymbol{L}_a/dt = 0$, meaning that the total angular momentum of particle plus agent is constant, or conserved. This principle may be generalized to include all interactions between bodies of any kind, acting by way of forces of any kind. Total angular momentum is always conserved. The law of conservation of angular momentum is one of the most important principles in all of physics.

Motion of a group of particles

CENTRE OF MASS

The word particle has been used in this article to signify an object whose entire mass is concentrated at a point in space. In the real world, however, there are no particles of this kind. All real bodies have sizes and shapes. Furthermore, as Newton believed and is now known, all bodies are in fact compounded of smaller bodies called atoms. Therefore, the science of mechanics must deal not only with particles but also with more complex bodies that may be thought of as collections of particles.

To take a specific example, the orbit of a planet around the Sun was discussed earlier as if the planet and the Sun were each concentrated at a point in space. In reality, of course, each is a substantial body. However, because each is nearly spherical in shape, it turns out to be permissible, for the purposes of this problem, to treat each body as if its mass were concentrated at its centre. This is an example of an idea that is often useful in discussing bodies of all kinds: the centre of mass. The centre of mass of a uniform sphere is located at the centre of the sphere. For many purposes (such as the one cited above) the sphere may be treated as if all its mass were concentrated at its centre of mass.

Centre of mass of a sphere

To extend the idea further, consider the Earth and the Sun not as two separate bodies but as a single system of two bodies interacting with one another by means of the force of gravity. In the previous discussion of circular orbits, the Sun was assumed to be at rest at the centre of the orbit, but, according to Newton's third law, it must actually be accelerated by a force due to the Earth that is equal and opposite to the force that the Sun exerts on the Earth. In other words, considering only the Sun and Earth (ignoring, for example, all the other planets), if M_S and M_E are, respectively, the masses of the Sun and the Earth, and if $\boldsymbol{a}_S$ and $\boldsymbol{a}_E$ are their respective accelerations, then combining Newton's second and third laws results in the equation $M_S\boldsymbol{a}_S = -M_E\boldsymbol{a}_E$. Writing each $\boldsymbol{a}$ as $d\boldsymbol{v}/dt$, this equation is easily manipulated to give

$$\frac{d}{dt}(M_S\boldsymbol{v}_S + M_E\boldsymbol{v}_E) = 0, \tag{50}$$

or

$$M_S\boldsymbol{v}_S + M_E\boldsymbol{v}_E = \text{constant}. \tag{51}$$

This remarkable result means that, as the Earth orbits the Sun and the Sun moves in response to the Earth's gravitational attraction, the entire two-body system has constant linear momentum, moving in a straight line at constant speed. Without any loss of generality, one can imagine observing the system from a frame of reference moving along with that same speed and direction. This is sometimes called the centre-of-mass frame. In this frame, the momentum of the two-body system—*i.e.*, the constant in equation (51)—is equal to zero. Writing each of the $\boldsymbol{v}$'s as the corresponding $d\boldsymbol{r}/dt$, equation (51) may be expressed in the form

$$\frac{d}{dt}(M_S\boldsymbol{r}_S + M_E\boldsymbol{r}_E) = 0. \tag{52}$$

Thus, $M_S\boldsymbol{r}_S$ and $M_E\boldsymbol{r}_E$ are two vectors whose vector sum does not change with time. The sum is defined to be the constant vector $M\boldsymbol{R}$, where M is the total mass of the system and equals $M_S + M_E$. Thus,

$$M\boldsymbol{R} = M_S\boldsymbol{r}_S + M_E\boldsymbol{r}_E. \tag{53}$$

This procedure defines a constant vector $\boldsymbol{R}$, from any arbitrarily chosen point in space. The relation between vectors $\boldsymbol{R}$, $\boldsymbol{r}_S$, and $\boldsymbol{r}_E$ is shown in Figure 12. The fact that $\boldsymbol{R}$ is constant (although $\boldsymbol{r}_S$ and $\boldsymbol{r}_E$ are not constant) means that, rather than the Earth orbiting the Sun, the Earth and Sun are both orbiting an imaginary point fixed in space. This point is known as the centre of mass of the two-body system.

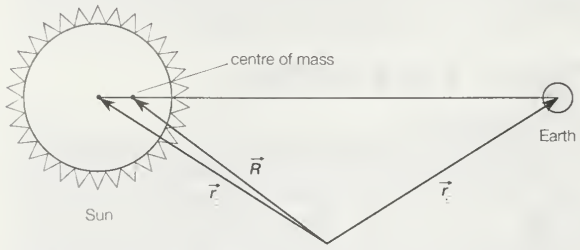

Figure 12: The centre of mass of the two-body Earth-Sun system.

Knowing the masses of the two bodies ($M_S = 1.99 \times 10^{30}$ kilograms, $M_E = 5.98 \times 10^{24}$ kilograms), it is easy to find the position of the centre of mass. The origin of the coordinate system may be chosen to be located at the centre of mass merely by defining $\boldsymbol{R} = 0$. Then $r_S = (M_E/M_S)\ r_E \approx 450$ kilometres, when r_E is rounded to 1.5×10^8 km. A few hundred kilometres is so small compared to r_E that, for all practical purposes, no appreciable error occurs when r_S is ignored and the Sun is assumed to be stationary at the centre of the orbit.

Centre of mass for an N-body system

With this example as a guide, it is now possible to define the centre of mass of any collection of bodies. Assume that there are N bodies altogether, each labeled with numbers ranging from 1 to N, and that the vector from an arbitrary origin to the ith body—where i is some number between 1 and N—is $\boldsymbol{r}_i$, as shown in Figure 13. Let the mass of the ith body be m_i. Then the total mass of the N-body system is

$$m = \sum_{i=1}^{N} m_i, \tag{54}$$

and the centre of mass of the system is found at the end of a vector $\boldsymbol{R}$ given by

$$m\boldsymbol{R} = \sum_{i=1}^{N} m_i \boldsymbol{r}_i, \tag{55}$$

as illustrated in Figure 13. This definition applies regardless of whether the N bodies making up the system are the stars in a galaxy, the atoms in a rigid body, larger and arbitrarily chosen segments of a rigid body, or any other system of masses. According to equation (55), the vector to the centre of mass of any system is a kind of weighted average of the vectors to all the components of the system.

As will be demonstrated in the sections that follow, the statics and dynamics of many complicated bodies or systems may often be understood by simply applying Newton's laws as if the system's mass were concentrated at the centre of mass.

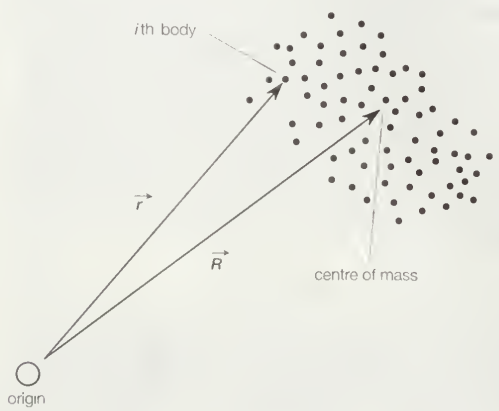

Figure 13: The centre of mass of an N-body system (see text).

CONSERVATION OF MOMENTUM

Newton's second law, in its most general form, says that the rate of a change of a particle's momentum $\boldsymbol{p}$ is given by the force acting on the particle; *i.e.*, $\boldsymbol{F} = d\boldsymbol{p}/dt$. If there is no force acting on the particle, then, since $d\boldsymbol{p}/dt = 0$, $\boldsymbol{p}$ must be constant, or conserved. This observation is merely a restatement of Newton's first law, the principle of inertia: if there is no force acting on a body, it moves at constant speed in a straight line.

Now suppose that an external agent applies a force $\boldsymbol{F}_a$ to the particle so that $\boldsymbol{p}$ changes according to

$$\frac{d\boldsymbol{p}}{dt} = \boldsymbol{F}_a. \tag{56}$$

According to Newton's third law, the particle must apply an equal and opposite force $-\boldsymbol{F}_a$ to the external agent. The momentum $\boldsymbol{p}_a$ of the external agent therefore changes according to

$$\frac{d\boldsymbol{p}_a}{dt} = -\boldsymbol{F}_a. \tag{57}$$

Adding together equations (56) and (57) results in the equation

$$\frac{d}{dt}(\boldsymbol{p} + \boldsymbol{p}_a) = 0. \tag{58}$$

The force applied by the external agent changes the momentum of the particle, but at the same time the momentum of the external agent must also change in such a way that the total momentum of both together is constant, or conserved. This idea may be generalized to give the law of conservation of momentum: in all the interactions between all the bodies in the universe, total momentum is always conserved.

Conservation of momentum

It is useful in this light to examine the behaviour of a complicated system of many parts. The centre of mass of the system may be found using equation (55). Differentiating with respect to time gives

$$m\boldsymbol{v} = \sum_{i=1}^{N} m_i \boldsymbol{v}_i, \tag{59}$$

where $\boldsymbol{v} = d\boldsymbol{R}/dt$ and $\boldsymbol{v}_i = d\boldsymbol{r}_i/dt$. Note that $m_i\boldsymbol{v}_i$ is the momentum of the ith part of the system, and $m\boldsymbol{v}$ is the momentum that the system would have if all its mass (*i.e.*, m) were concentrated at its centre of mass, the point whose velocity is $\boldsymbol{v}$. Thus, the momentum associated with the centre of mass is the sum of the momenta of the parts.

Suppose now that there is no external agent applying a force to the entire system. Then the only forces acting on the system are those exerted by the parts on one another. These forces may accelerate the individual parts. Differentiating equation (59) with respect to time gives

$$m\frac{d\boldsymbol{v}}{dt} = \sum_{i=1}^{N} m_i \frac{d\boldsymbol{v}_i}{dt} = \sum_{i=1}^{N} \boldsymbol{F}_i, \tag{60}$$

where $\boldsymbol{F}_i$ is the net force, or the sum of the forces, exerted by all the other parts of the body on the ith part. $\boldsymbol{F}_i$ is defined mathematically by the equation

$$\boldsymbol{F}_i = \sum_{j=1}^{N} \boldsymbol{F}_{ij}, \tag{61}$$

where $\boldsymbol{F}_{ij}$ represents the force on body i due to body j (the force on body i due to itself, $\boldsymbol{F}_{ii}$, is zero). The motion of the centre of mass is then given by the complicated-looking formula

$$m\frac{d\boldsymbol{v}}{dt} = \sum_{i=1}^{N}\left(\sum_{j=1}^{N} \boldsymbol{F}_{ij}\right). \tag{62}$$

This complicated formula may be greatly simplified, however, by noting that Newton's third law requires that for every force $\boldsymbol{F}_{ij}$ exerted by the jth body on the ith body, there is an equal and opposite force $-\boldsymbol{F}_{ij}$ exerted by the ith body on the jth body. In other words, every term in the double sum has an equal and opposite term. The double summation on the right-hand side of equation (61) always adds up to zero. This result is true regardless of the complexity of the system, the nature of the forces acting between the parts, or the motions of the parts. In short, in the absence of external forces acting

on the system as a whole, $m dv/dt = 0$, which means that the momentum of the centre of mass of the system is always conserved. Having determined that momentum is conserved whether or not there is an external force acting, one may conclude that the total momentum of the universe is always conserved.

COLLISIONS

A collision is an encounter between two bodies that alters at least one of their courses. Altering the course of a body requires that a force be applied to it. Thus, each body exerts a force on the other. These forces of interaction may operate at some distance, as do the gravitational and electromagnetic forces, or the bodies may appear to make physical contact. However, even apparent contact between two bodies is only a macroscopic manifestation of microscopic forces that act between atoms some distance apart. There is no fundamental distinction between physical contact and interaction at a distance.

Significance of understanding collision mechanics

The importance of understanding the mechanics of collisions is obvious to anyone who has ever driven an automobile. In modern physics, however, collisions are important for a different reason. The current understanding of the subatomic particles of which atoms are composed is derived entirely from studying the results of collisions among them. Thus, in modern physics, the description of collisions is a significant part of the understanding of matter. These descriptions are quantum mechanical rather than classical, but they are nevertheless closely based on principles that arise out of classical mechanics.

It is possible in principle to predict the result of a collision using Newton's second law directly. Suppose that two bodies are going to collide and that $\boldsymbol{F}$, the force of interaction between them, is known to be a function of r, the distance between them. Then, if it is known that, say, one particle has incident momentum $\boldsymbol{p}$, the problem is solved if the final momentum $\boldsymbol{p} + \Delta\boldsymbol{p}$ can be determined. Inverting Newton's second law, $\boldsymbol{F} = d\boldsymbol{p}/dt$, the change in momentum is given by

$$\Delta\boldsymbol{p} = \int_{-\infty}^{\infty} \boldsymbol{F} dt. \tag{63}$$

Impulse

This integral is known as the impulse imparted to the particle. In order to perform the integral, it is necessary to know $\boldsymbol{r}$ at all times so that $\boldsymbol{F}$ may be known at all times. More realistically, $\Delta\boldsymbol{p}$ is the sum of a series of small steps, such that

$$\delta\boldsymbol{p} = \boldsymbol{F}\delta t, \tag{64}$$

where $\boldsymbol{F}$ depends on the instantaneous distance between the particles. Because $\boldsymbol{p} = m\boldsymbol{v} = m d\boldsymbol{r}/dt$, the change in $\boldsymbol{r}$ in this step is

$$\delta\boldsymbol{r} = \frac{\boldsymbol{p}}{m}\delta t. \tag{65}$$

At the next step, there is a new distance, $\boldsymbol{r} + \delta\boldsymbol{r}$, giving a new value of the force in equation (64) and a new momentum, $\boldsymbol{p} + \delta\boldsymbol{p}$, in equation (65). This method of analyzing collisions is used in numerical calculations on digital computers.

To predict the result of a collision analytically (rather than numerically) it is often most useful to apply conservation laws. In any collision (as in any other phenomenon), energy, momentum, and angular momentum are always conserved. Judicious application of these laws may be extremely useful because they do not depend in any way on the detailed nature of the interaction (*i.e.*, the force as a function of distance).

This point can be illustrated by the following example. A collision is to take place between two bodies of the same mass m. One of the bodies is initially at rest (its momentum is zero). The other has initial momentum $\boldsymbol{p}_0$. After the collision, the body previously at rest has momentum $\boldsymbol{p}_1$, and the body initially in motion has momentum $\boldsymbol{p}_2$. Since momentum is conserved, the total momentum after the collision, $\boldsymbol{p}_1 + \boldsymbol{p}_2$, must be equal to the total momentum before the collision, $\boldsymbol{p}_0$; that is,

$$\boldsymbol{p}_0 = \boldsymbol{p}_1 + \boldsymbol{p}_2. \tag{66}$$

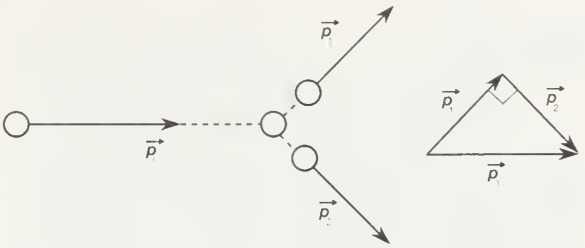

Figure 14: Collision between two particles of equal mass.

Equation (66) is the equation of a vector triangle, as shown in Figure 14. However, $\boldsymbol{p}_1$ and $\boldsymbol{p}_2$ are not determined by this condition; they are only constrained by it.

Although energy is always conserved, the kinetic energy of the incident body is not always converted entirely into the kinetic energy of the two bodies after the collision. For example, if the bodies are microscopic (say, two identical atoms), the collision may cause one or both to be excited into a state of higher internal energy than it started with. Such an event would leave correspondingly less kinetic energy for the outgoing atoms. In fact, it is precisely by studying the trajectories of outgoing projectiles in collisions like these that physicists are able to determine the possible excited states of microscopic particles.

In a collision between macroscopic objects, some of the kinetic energy is always converted to heat. Heat is the energy of random vibrations of the atoms and molecules that constitute the bodies. However, if the amount of heat is negligible compared to the initial kinetic energy, it may be ignored. Such a collision is said to be elastic.

Elastic collisions

Suppose the collision described above between two bodies, each of mass m, is between billiard balls, and suppose it is elastic (a reasonably good approximation of real billiard balls). The kinetic energy of the incident ball is then equal to the sum of the kinetic energies of the outgoing balls. According to equation (3), the kinetic energy of a moving object is given by $K = \frac{1}{2}mv^2$, where v is the speed of the ball (technically, the energy associated with the fact that the ball is rolling as well as translating is ignored here; see below *Rotation about a moving axis*). Equation (3) may be written in a particularly useful form by recognizing that since $p = mv$

$$K = \frac{1}{2}mv^2 = \frac{p^2}{2m}. \tag{67}$$

Then the conservation of kinetic energy may be written

$$\frac{p_0^2}{2m} = \frac{p_1^2}{2m} + \frac{p_2^2}{2m}, \tag{68}$$

or, canceling the factors $2m$,

$$p_0^2 = p_1^2 + p_2^2. \tag{69}$$

Comparing this result with equation (66) shows that the vector triangle is pythagorean; p_1 and p_2 are perpendicular. This result is well known to all experienced pool players. Notice that it was possible to arrive at this result without any knowledge of the forces that act when billiard balls collide.

RELATIVE MOTION

A collision between two bodies can always be described in a frame of reference in which the total momentum is zero. This is the centre-of-mass (or centre-of-momentum) frame mentioned earlier. Then, for example, in the collision between two bodies of the same mass discussed above, the two bodies always have equal and opposite velocities, as shown in Figure 15. It should be noted that, in this frame of reference, the outgoing momenta are antiparallel and not perpendicular.

Any collection of bodies may similarly be described in a frame of reference in which the total momentum is zero. This frame is simply the one in which the centre of mass is at rest. This fact is easily seen by differentiating equation (55) with respect to time, giving

$$m\frac{d\boldsymbol{R}}{dt} = \sum_{i=1}^{N} m_i \frac{d\boldsymbol{r}_i}{dt}. \tag{70}$$

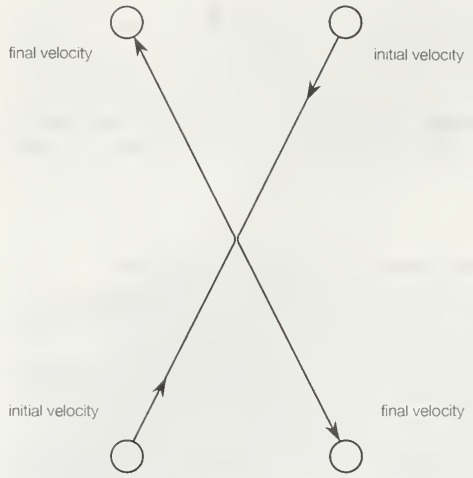

Figure 15: Collision between two particles of equal mass as seen from the centre-of-mass frame of reference.

The right-hand side is the sum of the momenta of all the bodies. It is equal to zero if the velocity of the centre of mass, $d\boldsymbol{R}/dt$, is equal to zero.

Principle of Galilean relativity

If Newton's second law is correct in any frame of reference, it will also appear to be correct to an observer moving with any constant velocity with respect to that frame. This principle, called the principle of Galilean relativity, is true because, to the moving observer, the same constant velocity seems to have been added to the velocity of every particle in the system. This change does not affect the accelerations of the particles (since the added velocity is constant, not accelerated) and therefore does not change the apparent force (mass times acceleration) acting on each particle. That is why it is permissible to describe a problem from the centre-of-momentum frame (provided that the centre of mass is not accelerated) or from any other frame moving at constant velocity with respect to it.

If this principle is strictly correct, the fundamental forces of physics should not contain any particular speed. This must be true because the speed of any object will be different to observers in different but equally good frames of reference, but the force should always be the same. It turns out, according to the theory of James Clerk Maxwell, that there is an intrinsic speed in the force laws of electricity and magnetism: the speed of light appears in the forces between electric charges and between magnetic poles. This discrepancy was ultimately resolved by Albert Einstein's special theory of relativity. According to the special theory of relativity, Newtonian mechanics breaks down when the relative speed between particles approaches the speed of light (see below *Relativistic mechanics*).

COUPLED OSCILLATORS

In the section on simple harmonic oscillators, the motion of a single particle held in place by springs was considered. In this section, the motion of a group of particles bound by springs to one another is discussed. The solutions of this seemingly academic problem have far-reaching implications in many fields of physics. For example, a system of particles held together by springs turns out to be a useful model of the behaviour of atoms mutually bound in a crystalline solid.

To begin with a simple case, consider two particles in a line, as shown in Figure 16. Each particle has mass m, each spring has spring constant k, and motion is restricted to the horizontal, or x, direction. Even this elementary system is capable of surprising behaviour, however. For instance, if one particle is held in place while the other is displaced, and then both are released, the displaced particle immediately begins to execute simple harmonic motion. This motion, by stretching the spring between the particles, starts to excite the second particle into motion. Gradually the energy of motion passes from the first particle to the second until a point is reached at which the first particle is at rest and only the second is oscillating. Then the process starts all over again, the energy passing in the opposite direction.

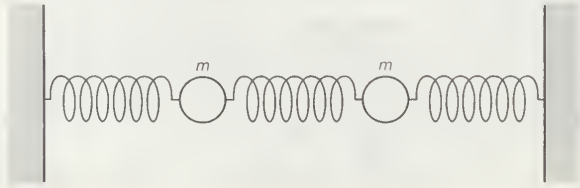

Figure 16: Coupled oscillators (see text).

To analyze the possible motions of the system, one writes equations similar to equation (11), giving the acceleration of each particle owing to the forces acting on it. There is one equation for each particle (two equations in this case). The force on each particle depends not only on its displacement from its equilibrium position but also on its distance from the other particle, since the spring between them stretches or compresses according to that distance. For this reason the motions are coupled, the solution of each equation (the motion of each particle) depending on the solution of the other (the motion of the other).

Analyzing the system yields the fact that there are two special states of motion in which both particles are always in oscillation with the same frequency. In one state, the two particles oscillate in opposite directions with equal and opposite displacements from equilibrium at all times. In the other state, both particles move together, so that the spring between them is never stretched or compressed. The first of these motions has higher frequency than the second because the centre spring contributes an increase in the restoring force.

Normal modes

These two collective motions, at different, definite frequencies, are known as the normal modes of the system.

If a third particle is inserted into the system together with another spring, there will be three equations to solve, and the result will be three normal modes. A large number N of particles in a line will have N normal modes. Each normal mode has a definite frequency at which all the particles oscillate. In the highest frequency mode each particle moves in the direction opposite to both of its neighbours. In the lowest frequency mode, neighbours move almost together, barely disturbing the springs between them. Starting from one end, the amplitude of the motion gradually builds up, each particle moving a bit more than the one before, reaching a maximum at the centre, and then decreasing again. A plot of the amplitudes, shown in Figure 17, basically describes one-half of a sine wave from one end of the system to the other. The next mode is $^3/_2$ of a sine wave, and so on to the highest frequency mode, which may be visualized as $(2N-1)/2$ sine waves. If the vibrations were up and down rather than side to side, these modes would be identical to the fundamental and harmonic vibrations excited by plucking a guitar string.

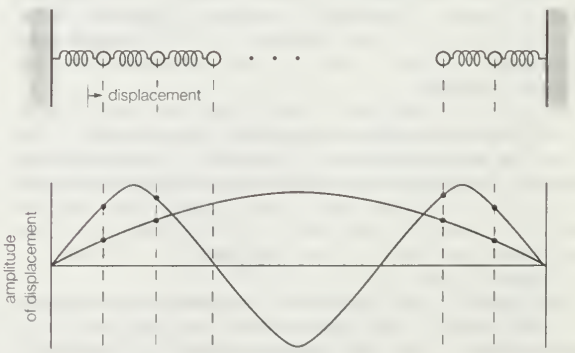

Figure 17: Normal modes (see text).

The atoms of a crystal are held in place by mutual forces of interaction that oppose any disturbance from equilibrium positions, just as the spring forces in the example above. For small displacements of the atoms, they behave mathematically just like spring forces—*i.e.*, they obey Hookes' law, equation (10). Each atom is free to move in three dimensions rather than one, however;

Excitation of modes of a crystal

therefore each atom added to a crystal adds three normal modes. In a typical crystal at ordinary temperature, all these modes are always excited by random thermal energy. The lower-frequency, longer-wavelength modes may also be excited mechanically. These are called sound waves.

Rigid bodies

STATICS

Statics is the study of bodies and structures that are in equilibrium. For a body to be in equilibrium, there must be no net force acting on it. In addition, there must be no net torque acting on it. Figure 18A shows a body in equilibrium under the action of equal and opposite forces. Figure 18B shows a body acted on by equal and opposite forces that produce a net torque, tending to start it rotating. It is therefore not in equilibrium.

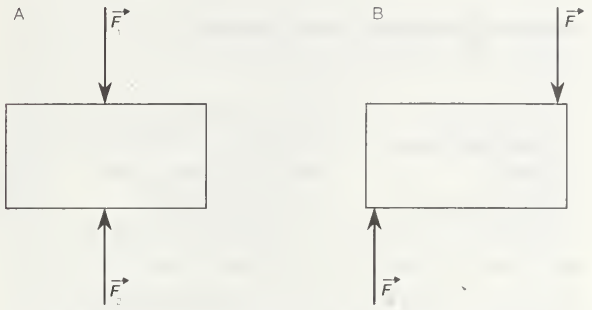

Figure 18: (A) A body in equilibrium under equal and opposite forces. (B) A body not in equilibrium under equal and opposite forces.

When a body has a net force and a net torque acting on it owing to a combination of forces, all the forces acting on the body may be replaced by a single (imaginary) force called the resultant, which acts at a single point on the body, producing the same net force and the same net torque. The body can be brought into equilibrium by applying to it a real force at the same point, equal and opposite to the resultant. This force is called the equilibrant. An example is shown in Figure 19.

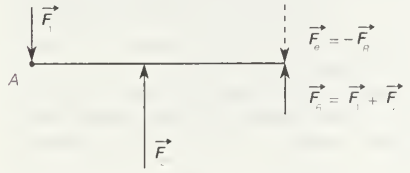

Figure 19: The resultant force (F_R) produces the same net force and the same net torque about point A as $F_1 + F_2$; the body can be brought into equilibrium by applying the equilibriant force F_e.

The torque on a body due to a given force depends on the reference point chosen, since the torque τ by definition equals $r \times F$, where r is a vector from some chosen reference point to the point of application of the force. Thus, for a body to be at equilibrium, not only must the net force on it be equal to zero but the net torque with respect to any point must also be zero. Fortunately, it is easily shown for a rigid body that, if the net force is zero and the net torque is zero with respect to any one point, then the net torque is also zero with respect to any other point in the frame of reference.

Rigid bodies

A body is formally regarded as rigid if the distance between any set of two points in it is always constant. In reality no body is perfectly rigid. When equal and opposite forces are applied to a body, it is always deformed slightly. The body's own tendency to restore the deformation has the effect of applying counterforces to whatever is applying the forces, thus obeying Newton's third law. Calling a body rigid means that the changes in the dimensions of the body are small enough to be neglected, even though the force produced by the deformation may not be neglected.

Equal and opposite forces acting on a rigid body may act so as to compress the body (Figure 20A) or to stretch it

Figure 20: (A) Compression produced by equal and opposite forces. (B) Tension produced by equal and opposite forces.

(Figure 20B). The bodies are then said to be under compression or under tension, respectively. Strings, chains, and cables are rigid under tension but may collapse under compression. On the other hand, certain building materials, such as brick and mortar, stone, or concrete, tend to be strong under compression but very weak under tension.

Application of statics

The most important application of statics is to study the stability of structures, such as edifices and bridges. In these cases, gravity applies a force to each component of the structure as well as to any bodies the structure may need to support. The force of gravity acts on each bit of mass of which each component is made, but for each rigid component it may be thought of as acting at a single point, the centre of gravity, which is in these cases the same as the centre of mass.

To give a simple but important example of the application of statics, consider the two situations shown in Figure 21. In each case, a mass m is supported by two symmetric members, each making an angle θ with respect to the horizontal. In Figure 21A the members are under tension; in Figure 21B they are under compression. In either case, the force acting along each of the members is shown to be

$$F = \frac{mg}{2 \sin \theta}. \qquad (71)$$

The force in either case thus becomes intolerably large if the angle θ is allowed to be very small. In other words, the mass cannot be hung from a perfectly horizontal member.

The ancient Greeks built magnificent stone temples; however, the horizontal stone slabs that constituted the roofs of the temples could not support even their own weight over more than a very small span. For this reason, one characteristic that identifies a Greek temple is the many closely spaced pillars needed to hold up the flat roof. The problem posed by equation (71) was solved by the ancient Romans, who incorporated into their architecture the arch, a structure that supports its weight by compression, corresponding to Figure 21B.

A suspension bridge illustrates the use of tension. The weight of the span and any traffic on it is supported by cables, which are placed under tension by the weight. Corresponding to Figure 21A, the cables are not stretched to be horizontal, but rather they are always hung so as to have substantial curvature.

It should be mentioned in passing that equilibrium under static forces is not sufficient to guarantee the stability of a structure. It must also be stable against perturbations such as the additional forces that might be imposed, for example, by winds or by earthquakes. Analysis of the stability of structures under such perturbations is an important part of the job of an engineer or architect.

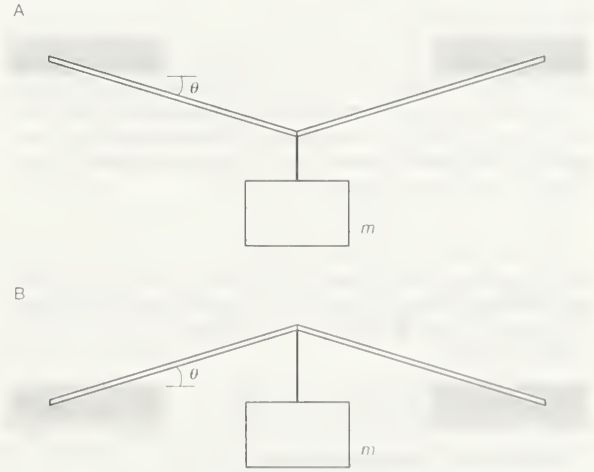

Figure 21: (A) A body supported by two rigid members under tension. (B) A body supported by two rigid members under compression.

ROTATION ABOUT A FIXED AXIS

Factors affecting inertial resistance

Consider a rigid body that is free to rotate about an axis fixed in space. Because of the body's inertia, it resists being set into rotational motion, and equally important, once rotating, it resists being brought to rest. Exactly how that inertial resistance depends on the mass and geometry of the body is discussed here.

Take the axis of rotation to be the z-axis. A vector in the x-y plane from the axis to a bit of mass fixed in the body makes an angle θ with respect to the x-axis. If the body is rotating, θ changes with time, and the body's angular frequency is

$$\omega = \frac{d\theta}{dt}; \tag{72}$$

ω is also known as the angular velocity. If ω is changing in time, there is also an angular acceleration α, such that

$$\alpha = \frac{d\omega}{dt}. \tag{73}$$

Because linear momentum p is related to linear speed v by $p = mv$, where m is the mass, and because force F is related to acceleration a by $F = ma$, it is reasonable to assume that there exists a quantity I that expresses the rotational inertia of the rigid body in analogy to the way m expresses the inertial resistance to changes in linear motion. One would expect to find that the angular momentum is given by

$$L = I\omega \tag{74}$$

and that the torque (twisting force) is given by

$$\tau = I\alpha. \tag{75}$$

One can imagine dividing the rigid body into bits of mass labeled m_1, m_2, m_3, and so on. Let the bit of mass at the tip of the vector be called m_i, as indicated in Figure 22.

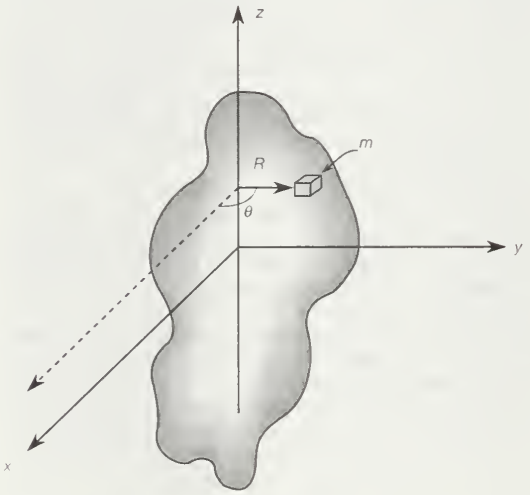

Figure 22: Rotation around a fixed axis.

If the length of the vector from the axis to this bit of mass is R_i, then m_i's linear velocity v_i equals ωR_i (see equation [31]), and its angular momentum L_i equals $m_i v_i R_i$ (see equation [44]), or $m_i R_i^2 \omega$. The angular momentum of the rigid body is found by summing all the contributions from all the bits of mass labeled $i = 1, 2, 3 \ldots$:

$$L = \left(\sum_i m_i R_i^2\right)\omega. \tag{76}$$

In a rigid body, the quantity in parentheses in equation (76) is always constant (each bit of mass m_i always remains the same distance R_i from the axis). Thus if the motion is accelerated, then

$$\frac{dL}{dt} = \left(\sum_i m_i R_i^2\right)\frac{d\omega}{dt}. \tag{77}$$

Recalling that $\tau = dL/dt$, one may write

$$\tau = \left(\sum_i m_i R_i^2\right)\alpha. \tag{78}$$

(These equations may be written in scalar form, since L and τ are always directed along the axis of rotation in this discussion.) Comparing equations (76) and (78) with (74) and (75), one finds that

$$I = \sum_i m_i R_i^2. \tag{79}$$

Moment of inertia

The quantity I is called the moment of inertia.

According to equation (79), the effect of a bit of mass on the moment of inertia depends on its distance from the axis. Because of the factor R_i^2, mass far from the axis makes a bigger contribution than mass close to the axis. It is important to note that R_i is the distance from the axis, not from a point. Thus, if x_i and y_i are the x and y coordinates of the mass m_i, then $R_i^2 = x_i^2 + y_i^2$, regardless of the value of the z coordinate. The moments of inertia of some simple uniform bodies are given in the table.

Moments of Inertia for Uniform Bodies

body	axis	I
Thin rod (length L)	perpendicular axis through centre	$\frac{1}{12}ML^2$
Thin ring (radius R)	perpendicular axis through centre	MR^2
Solid circular cylinder	axis of cylinder	$\frac{1}{2}MR^2$
Thin disk	transverse axis through centre	$\frac{1}{4}MR^2$
Solid sphere	any axis through centre	$\frac{2}{5}MR^2$
Thin spherical shell	any axis through centre	$\frac{2}{3}MR^2$
Rectangular plate (length a, height b)	axis through centre perpendicular to the plate	$\frac{1}{12}M(a^2 + b^2)$

The moment of inertia of any body depends on the axis of rotation. Depending on the symmetry of the body, there may be as many as three different moments of inertia about mutually perpendicular axes passing through the centre of mass. If the axis does not pass through the centre of mass, the moment of inertia may be related to that about a parallel axis that does so. Let I_c be the moment of inertia about the parallel axis through the centre of mass, r the distance between the two axes, and M the total mass of the body. Then

$$I = I_c + Mr^2. \tag{80}$$

In other words, the moment of inertia about an axis that does not pass through the centre of mass is equal to the moment of inertia for rotation about an axis through the centre of mass (I_c) plus a contribution that acts as if the mass were concentrated at the centre of mass, which then rotates about the axis of rotation.

The dynamics of rigid bodies rotating about fixed axes may be summarized in three equations. The angular momentum is $L = I\omega$, the torque is $\tau = I\alpha$, and the kinetic energy is $K = \frac{1}{2}I\omega^2$.

ROTATION ABOUT A MOVING AXIS

Combined translation and rotation

The general motion of a rigid body tumbling through space may be described as a combination of translation of the body's centre of mass and rotation about an axis through the centre of mass. The linear momentum of the body of mass M is given by

$$\boldsymbol{p} = M\boldsymbol{v}_c \tag{81}$$

where $\boldsymbol{v}_c$ is the velocity of the centre of mass. Any change in the momentum is governed by Newton's second law, which states that

$$\boldsymbol{F} = \frac{d\boldsymbol{p}}{dt}, \tag{82}$$

where $\boldsymbol{F}$ is the net force acting on the body. The angular momentum of the body with respect to any reference point may be written as

$$\boldsymbol{L} = \boldsymbol{L}_c + \boldsymbol{r} \times \boldsymbol{p}, \tag{83}$$

where $\boldsymbol{L}_c$ is the angular momentum of rotation about an axis through the centre of mass, $\boldsymbol{r}$ is a vector from the reference point to the centre of mass, and $\boldsymbol{r} \times \boldsymbol{p}$ is therefore the angular momentum associated with motion of the centre of mass, acting as if all the body's mass were concentrated at that point. The quantity $\boldsymbol{L}_c$ in equation (83) is sometimes called the body's spin, and $\boldsymbol{r} \times \boldsymbol{p}$ is called the orbital angular momentum. Any change in the angular momentum of the body is given by the torque equation,

$$\tau = \frac{dL}{dt}. \tag{84}$$

An example of a body that undergoes both translational and rotational motion is the Earth, which rotates about an axis through its centre once per day while executing an orbit around the Sun once per year. Because the Sun exerts no torque on the Earth with respect to its own centre, the orbital angular momentum of the Earth is constant in time. However, the Sun does exert a small torque on the Earth with respect to the planet's centre, owing to the fact that the Earth is not perfectly spherical. The result is a slow shifting of the Earth's axis of rotation, known as the precession of the equinoxes (see below).

The kinetic energy of a body that is both translating and rotating is given by

$$K = \frac{1}{2}Mv_c^2 + \frac{1}{2}I\omega^2, \tag{85}$$

where I is the moment of inertia and ω is the angular velocity of rotation about the axis through the centre of mass.

A common example of combined rotation and translation is rolling motion, as exhibited by a billiard ball rolling on a table, or a ball or cylinder rolling down an inclined plane. Consider the latter example, illustrated in Figure 23. Motion is impelled by the force of gravity, which may be resolved into two components, F_N, which is normal to the plane, and F_p, which is parallel to it. In addition to gravity, friction plays an essential role. The force of friction, written as f, acts parallel to the plane, in opposition to the direction of motion, at the point of contact between the plane and the rolling body. If f is very small, the body will slide without rolling. If f is very large, it will prevent motion from occurring. The magnitude of f depends on the smoothness and composition of the body and the plane, and it is proportional to F_N, the normal component of the force.

Frictional force

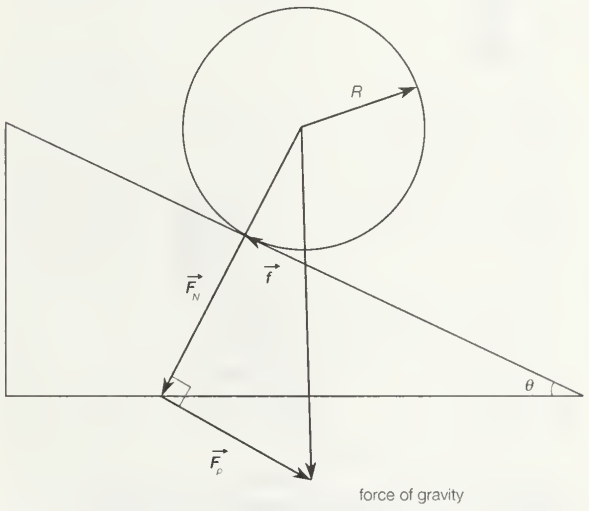

Figure 23: Rolling motion (see text).

Consider a case in which f is just large enough to cause the body (sphere or cylinder) to roll without slipping. The motion may be analyzed from the point of view of an axis passing through the point of contact between the rolling body and the plane. Remarkably, the point of contact may always be regarded to be instantaneously at rest. To understand why, suppose that the rolling body has radius R and angular velocity ω about its centre-of-mass axis. Then, with respect to its own axis, each point on the circular cross section in Figure 23 moves with instantaneous tangential linear speed $v_c = R\omega$. In particular, the point of contact is moving backward with this speed relative to the centre of mass. But with respect to the inclined plane, the centre of mass is moving forward with exactly this same speed. The net effect of the two equal and opposite speeds is that the point of contact is always instantaneously at rest. Therefore, although friction acts at that point, no work is done by friction, so mechanical energy (potential plus kinetic) may be regarded as conserved.

With respect to the axis through the point of contact, the torque is equal to RF_p, giving rise to an angular acceleration α given by $I_p\alpha = RF_p$, where I_p is the moment of inertia about the point-of-contact axis and can be determined by applying equation (80) relating moments of inertia about parallel axes ($I_p = I + MR^2$). Thus,

$$\alpha = \frac{RF_p}{I + MR^2}. \tag{86}$$

From this result, the motion of the body is easily obtained using the fact that the velocity of the centre of mass is $v_c = R\omega$ and hence the linear acceleration of the centre of mass is $a_c = R\alpha$.

Notice that, although without friction no angular acceleration would occur, the force of friction does not affect the magnitude of α. Because friction does no work, this same result may be obtained by applying energy conservation. The situation also may be analyzed entirely from the point of view of the centre of mass. In that case, the torque is $-fR$, but f also provides a linear force on the body. The f may then be eliminated by using Newton's second law and the fact that the torque equals the moment of inertia times the angular acceleration, once again leading to the same result.

One more interesting fact is hidden in the form of equation (86). The parallel component of the force of gravity is given by

$$F_p = Mg \sin\theta, \tag{87}$$

where θ is the angle of inclination of the plane. The moment of inertia about the centre of mass of any body of mass M may be written

$$I = Mk^2, \tag{88}$$

where k is a distance called the radius of gyration. Comparison to equation (79) shows that k is a measure of how far from the centre of mass the mass of the body is concentrated. Using equations (87) and (88) in equation (86), one finds that

Radius of gyration

$$\alpha = \frac{Rg \sin\theta}{k^2 + R^2}. \tag{89}$$

Thus, the angular acceleration of a body rolling down a plane does not depend on its total mass, although it does depend on its shape and distribution of mass. The same may be said of a_c, the linear acceleration of the centre of mass. The acceleration of a rolling ball, like the acceleration of a freely falling object, is independent of its mass. This observation helps to explain why Galileo was able to discover many of the basic laws of dynamics in gravity by studying the behaviour of balls rolling down inclined planes.

MOTION IN A ROTATING FRAME

Centrifugal force. According to the principle of Galilean relativity, if Newton's laws are true in any reference frame, they are also true in any other frame moving at constant velocity with respect to the first one. Conversely, they do not appear to be true in any frame accelerated with respect to the first. Instead, in an accelerated frame, objects appear to have forces acting on them that are not in fact present. These are called pseudoforces, as described above. Since rotational motion is always accelerated motion, pseudoforces may always be observed in rotating frames of reference.

As one example, a frame of reference in which the Earth is at rest must rotate once per year about the Sun. In this reference frame, the gravitational force attracting the Earth toward the Sun appears to be balanced by an equal and opposite outward force that keeps the Earth in stationary equilibrium. This outward pseudoforce, discussed above, is the centrifugal force.

The rotation of the Earth about its own axis also causes pseudoforces for observers at rest on the Earth's surface. There is a centrifugal force, but it is much smaller than the force of gravity. Its effect is that, at the Equator, where it is largest, the gravitational acceleration g is about 0.5 percent smaller than at the poles, where there is no centrifugal force. This same centrifugal force is responsible

for the fact that the Earth is slightly nonspherical, bulging just a bit at the Equator.

Pseudoforces can have real consequences. The oceanic tides on Earth, for example, are a consequence of centrifugal forces in the Earth-Moon and Earth-Sun systems. The Moon appears to be orbiting the Earth, but in reality both the Moon and the Earth orbit their common centre of mass. The centre of mass of the Earth-Moon system is located inside the Earth nearly three-fourths of the distance from the centre to the surface, or roughly 4,700 kilometres from the centre of the Earth. The Earth rotates about this point approximately once a month. The gravitational attraction of the Moon and the centrifugal force of this rotation are exactly balanced at the centre of the Earth. At the surface of the Earth closest to the Moon, the Moon's gravity is stronger than the centrifugal force. The ocean's waters, which are free to move in response to this unbalanced force, tend to build up a small bulge at that point. On the surface of the Earth exactly opposite the Moon, the centrifugal force is stronger than the Moon's gravity, and a small bulge of water tends to build up there as well. The water is correspondingly depleted at the points 90° on either side of these. Each day the Earth rotates beneath these bulges and troughs, which remain stationary with respect to the Earth-Moon system. The result is two high tides and two low tides every day every place on Earth. The Sun has a similar effect, but of only about half the size; it increases or decreases the size of the tides depending on its relative alignment with the Earth and Moon.

The tides

Coriolis force. The Coriolis force is a pseudoforce that operates in all rotating frames. One way to envision it is to imagine a rotating platform (such as a merry-go-round or a phonograph turntable) with a perfectly smooth surface and a smooth block sliding inertially across it. The block, having no (real) forces acting on it, moves in a straight line at constant speed in inertial space. However, the platform rotates under it, so that to an observer on the platform, the block appears to follow a curved trajectory, bending in the opposite direction to the motion of the platform. Since the motion is curved, and hence accelerated, there appears, to the observer, to be a force operating. That pseudoforce is called the Coriolis force.

The Coriolis force also may be observed on the surface of the Earth. For example, many science museums have a pendulum, called a Foucault pendulum, suspended from a long cable with markers to show that its plane of motion rotates slowly. The rotation of the plane of motion is caused by the Coriolis force. The effect is most easily imagined by picturing the pendulum swinging directly above the North Pole. The plane of its motion remains stationary in inertial space, while the Earth rotates once a day beneath it.

Effect on projectile motion

At lower latitudes, the effect is a bit more subtle, but it is still present. Imagine that, somewhere in the Northern Hemisphere, a projectile is fired due south. As viewed from inertial space, the projectile initially has an eastward component of velocity as well as a southward component because the gun that fired it, which is stationary on the surface of the Earth, was moving eastward with the Earth's rotation at the instant it was fired. However, since it was fired to the south, it lands at a slightly lower latitude, closer to the Equator. As one moves south, toward the Equator, the tangential speed of the Earth's surface due to its rotation increases because the surface is farther from the axis of rotation. Thus, although the projectile has an eastward component of velocity (in inertial space), it lands at a place where the surface of the Earth has a larger eastward component of velocity. Thus, to the observer on Earth, the projectile seems to curve slightly to the west. That westward curve is attributed to the Coriolis force. If the projectile were fired to the north, it would seem to curve eastward.

The same analysis applied to a Foucault pendulum explains why its plane of motion tends to rotate in the clockwise direction anywhere in the Northern Hemisphere and in the counterclockwise direction in the Southern Hemisphere. Storms, known as cyclones, tend to rotate in the opposite direction in each hemisphere, also due to the Coriolis force. Air moves in all directions toward a low-pressure centre. In the Northern Hemisphere, air moving up from the south is deflected eastward, while air moving down from the north is deflected westward. This effect tends to give cyclones a counterclockwise circulation in the Northern Hemisphere. In the Southern Hemisphere, cyclones tend to circulate in the clockwise direction.

SPINNING TOPS AND GYROSCOPES

Figure 24A shows a wheel that is weighted in its rim to maximize its moment of inertia I and that is spinning with angular frequency ω on a horizontal axle supported at both ends. As shown, it has an angular momentum L along the x direction equal to $I\omega$. Now suppose the support at point P is removed, leaving the axle supported only at one end. Gravity, acting on the mass of the wheel as if it were concentrated at the centre of mass, applies a downward force on the wheel. The wheel, however, does not fall. Instead, the axle remains (nearly) horizontal but rotates in the counterclockwise direction as seen from above (Figure 24B). This motion is called gyroscopic precession.

From (B) R P. Olenick, T M. Apostol, and D L. Goodstein, *The Mechanical Universe: Introduction to Mechanics and Heat* (1985), Cambridge University Press

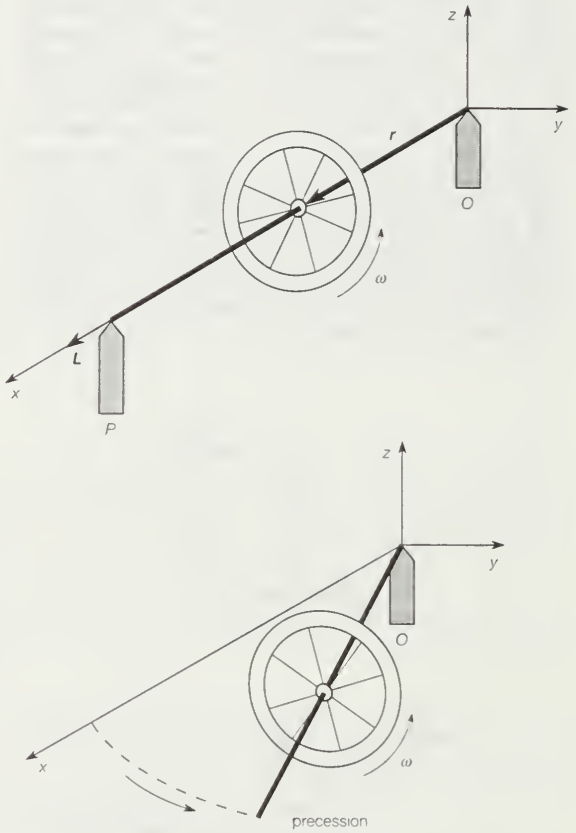

Figure 24: (A) A spinning wheel supported at both ends of an axle. (B) A spinning wheel supported at one end of an axle and exhibiting precession. (See text.)

Precession

Horizontal precession occurs in this case because the gravitational force results in a torque with respect to the point of suspension, such that $\tau = r \times F$ and is directed, initially, in the positive y direction. The torque causes the angular momentum L to move toward that direction according to $\tau = dL/dt$. Because τ is perpendicular to L, it does not change the magnitude of the angular momentum, only its direction. As precession proceeds, the torque remains horizontal, and the angular momentum vector, continually redirected by the torque, executes uniform circular motion in the horizontal plane at a frequency Ω, the frequency of precession.

In reality, the motion is a bit more complicated than uniform precession in the horizontal plane. When the support at P is released, the centre of mass of the wheel initially drops slightly below the horizontal plane. This drop reduces the gravitational potential energy of the system, releasing kinetic energy for the orbital motion of the

centre of mass as it precesses. It also provides a small component of $\boldsymbol{L}$ in the negative z direction, which balances the angular momentum in the positive z direction that results from the orbital motion of the centre of mass. There can be no net angular momentum in the vertical direction because there is no component of torque in that direction.

One more complication: the initial drop of the centre of mass carries it too far for a stable plane of precession, and it tends to bounce back up after overshooting. This produces an up-and-down oscillation during precession, called nutation ("nodding"). In most cases, nutation is quickly damped by friction in the bearings, leaving uniform precession.

A spinning top undergoes all the motions described above. If it is initially set spinning with a vertical axis, there will be virtually no torque, and conservation of angular momentum will keep the axis vertical for a long time. Eventually, however, friction at the point of contact will require the centre of mass to lower itself, which can only happen if the axis tilts. The spinning will also slow down, making the tilting process easier. Once the top tilts, gravity produces a horizontal torque that leads to precession of the spin axis. The subsequent motion depends on whether the point of contact is fixed or free to slip on the horizontal plane. Vast tomes have been written on the motions of tops.

A gyroscope is a device that is designed to resist changes in the direction of its axis of spin. That purpose is generally accomplished by maximizing its moment of inertia about the spin axis and by spinning it at the maximum practical frequency. Each of these considerations has the effect of maximizing the magnitude of the angular momentum, thus requiring a larger torque to change its direction. It is quite generally true that the torque $\boldsymbol{\tau}$, the angular momentum $\boldsymbol{L}$, and the precession frequency $\boldsymbol{\Omega}$ (defined as a vector along the precession axis in the direction given by the right-hand rule) are related by

$$\boldsymbol{\tau} = \boldsymbol{\Omega} \times \boldsymbol{L}. \tag{90}$$

Equation (90), illustrated in Figure 25, is called the gyroscope equation.

Uses of gyroscopes

Gyroscopes are used for a variety of purposes, including navigation. Use of gyroscopes for this purpose is called inertial guidance. The gyroscope is suspended as nearly as possible at its centre of mass, so that gravity does not apply a torque that causes it to precess. The gyroscope tends therefore to point in a constant direction in space, allowing the orientation of the vehicle to be accurately maintained.

One further application of the gyroscope principle may be seen in the precession of the equinoxes. The Earth is a kind of gyroscope, spinning on its axis once each day. The Sun would apply no torque to the Earth if the Earth were perfectly spherical, but it is not. The Earth bulges slightly at the Equator. As indicated in Figure 26, the effect of the Sun's gravity on the near bulge (larger than it is on the far bulge) results in a net torque about the centre of the Earth. When the Earth is on the other side of the Sun, the net torque remains in the same direction. The torque

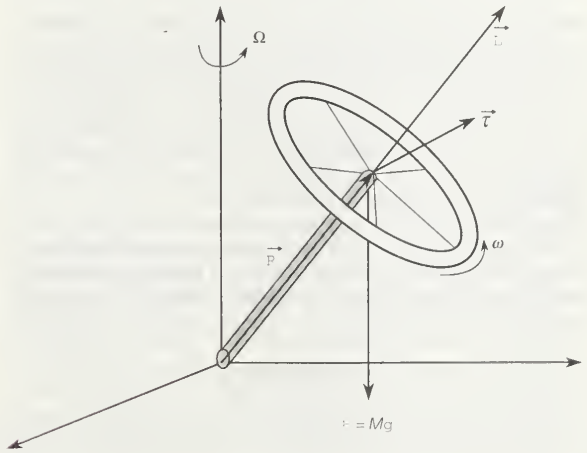

Figure 25: A gyroscope (see text).

Figure 26: Forces acting on equatorial bulges in (A) the summer and (B) the winter cause the axis of the Earth to precess (see text).

After R.P. Olenick, T.M. Apostol, and D.L. Goodstein, *The Mechanical Universe: Introduction to Mechanics and Heat* (1985), Cambridge University Press

is small but persistent. It causes the axis of the Earth to precess, about one revolution every 25,800 years.

Precession of the equinoxes

As seen from the Earth, the Sun passes through the plane of the Equator twice each year. These points are called the equinoxes, and on the days of the equinoxes the hours of daylight and night are equal. From antiquity it has been known that the point in the sky where the Sun intersects the plane of the Equator is not the same each year but rather drifts very slowly to the west. This ancient observation, first explained by Newton, is due to the precession of the Earth's axis.

Analytic approaches

Classical mechanics can, in essence, be reduced to Newton's laws, starting with the second law, in the form

$$\boldsymbol{F} = \frac{d\boldsymbol{p}}{dt}. \tag{91}$$

If the net force acting on a particle is $\boldsymbol{F}$, knowledge of $\boldsymbol{F}$ permits the momentum $\boldsymbol{p}$ to be found; and knowledge of $\boldsymbol{p}$ permits the position $\boldsymbol{r}$ to be found, by solving the equation

$$\frac{d\boldsymbol{r}}{dt} = \frac{\boldsymbol{p}}{m}. \tag{92}$$

These solutions give the components of $\boldsymbol{p}$—that is, p_x, p_y, and p_z—and the components of $\boldsymbol{r}$—x, y, and z—each as a function of time. To complete the solution, the value of each quantity—p_x, p_y, p_z, x, y, and z—must be known at some definite time, say, $t = 0$. If there is more than one particle, an equation in the form of equation (91) must be written for each particle, and the solution will involve finding the six variables x, y, z, p_x, p_y, and p_z, for each particle as a function of time, each once again subject to some initial condition. The equations may not be independent, however. For example, if the particles interact with one another, the forces will be related by Newton's third law. In this case (and others), the forces may also depend on time.

If the problem involves more than a very few particles, this method of solution quickly becomes intractable. Furthermore, in many cases it is not useful to express the problem purely in terms of particles and forces. Consider, for example, the problem of a sphere or cylinder rolling without slipping on a plane surface. Rolling without slipping is produced by friction due to forces acting between atoms in the rolling body and atoms in the plane, but the interactions are very complex; they probably are not fully understood even today, and one would like to be able to formulate and solve the problem without introducing them or needing to understand them. For all these reasons, methods that go beyond solving equations (91) and (92) have had to be introduced into classical mechanics.

The methods that have been introduced do not involve new physics. In fact, they are deduced directly from Newton's laws. They do, however, involve new concepts, new language to describe those concepts, and the adoption of powerful mathematical techniques. Some of those methods are briefly surveyed here.

CONFIGURATION SPACE

The position of a single particle is specified by giving its three coordinates, x, y, and z. To specify the positions of two particles, six coordinates are needed, x_1, y_1, z_1, x_2, y_2, z_2. If there are N particles, $3N$ coordinates will be needed. Imagine a system of $3N$ mutually orthogonal co-

ordinates in a $3N$-dimensional space (a space of more than three dimensions is a purely mathematical construction, sometimes known as a hyperspace). To specify the exact position of one single point in this space, $3N$ coordinates are needed. However, one single point can represent the entire configuration of all N particles in the problem. Furthermore, the path of that single point as a function of time is the complete solution of the problem. This $3N$-dimensional space is called configuration space.

Problem constraints

Configuration space is particularly useful for describing what is known as constraints on a problem. Constraints are generally ways of describing the effects of forces that are best not explicitly introduced into the problem. For example, consider the simple case of a falling body near the surface of the Earth. The equations of motion—equations (4), (5), and (6)—are valid only until the body hits the ground. Physically, this restriction is due to forces between atoms in the falling body and atoms in the ground, but, as a practical matter, it is preferable to say that the solutions are valid only for $z > 0$ (where $z = 0$ is ground level). This constraint, in the form of an inequality, is very difficult to incorporate directly into the equations of the problem. In the language of configuration space, however, one merely needs to specify that the problem is being solved only in the region of configuration space for which $z > 0$.

Notice that the constraint mentioned above, rolling without sliding on a plane, cannot easily be described in configuration space, since it is basically a condition on relative velocities of rotation and translation; but another constraint, that the body is restricted to motion along the plane, is easily described in configuration space.

Another type of constraint specifies that a body is rigid. Then, even though the body is composed of a very large number of atoms, it is not necessary to find separately the x, y, and z coordinate of each atom because these are related to those of the other atoms by the condition of rigidity. A careful analysis yields that, rather than needing $3N$ coordinates (where N may be, for example, 10^{24} atoms) only 6 are needed: 3 to specify the position of the centre of mass and 3 to give the orientation of the body. Thus, in this case, the constraint has reduced the number of independent coordinates from $3N$ to 6. Rather than restricting the behaviour of the system to a portion of the original $3N$-dimensional configuration space, it is possible to describe the system in a much simpler 6-dimensional configuration space. It should be noted, however, that the six coordinates are not necessarily all distances. In fact, the most convenient coordinates are three distances (the x, y, and z coordinates of the centre of mass of the body) and three angles, which specify the orientation of a set of axes fixed in the body relative to a set of axes fixed in space. This is an example of the use of constraints to reduce the number of dynamic variables in a problem (the x, y, and z coordinates of each particle) to a smaller number of generalized dynamic variables, which need not even have the same dimensions as the original ones.

THE PRINCIPLE OF VIRTUAL WORK

A special class of problems in mechanics involves systems in equilibrium. The problem is to find the configuration of the system, subject to whatever constraints there may be, when all forces are balanced. The body or system will be at rest (in the inertial rest frame of its centre of mass), meaning that it occupies one point in configuration space for all time. The problem is to find that point. One criterion for finding that point, which makes use of the calculus of variations, is called the principle of virtual work.

Principle of virtual work

According to the principle of virtual work, any infinitesimal virtual displacement in configuration space, consistent with the constraints, requires no work. A virtual displacement means an instantaneous change in coordinates (a real displacement would require finite time during which particles might move and forces might change). To express the principle, label the generalized coordinates $r_1, r_2, \ldots, r_i, \ldots$. Then if F_i is the net component of generalized force acting along the coordinate r_i,

$$\sum_i F_i dr_i = 0. \tag{93}$$

Here, $F_i dr_i$ is the work done when the generalized coordinate is changed by the infinitesimal amount dr_i. If r_i is a real coordinate (say, the x coordinate of a particle), then F_i is a real force. If r_i is a generalized coordinate (say, an angular displacement of a rigid body), then F_i is the generalized force such that $F_i dr_i$ is the work done (for an angular displacement, F_i is a component of torque).

Take two simple examples to illustrate the principle. First consider two particles that are restricted to motion in the x direction and are constrained by a taut string connecting them. If their x coordinates are called x_1 and x_2, then $F_1 dx_1 + F_2 dx_2 = 0$ according to the principle of virtual work. But the taut string requires that the particles be displaced the same amount, so that $dx_1 = dx_2$, with the result that $F_1 + F_2 = 0$. The particles might be in equilibrium, for example, under equal and opposite forces, but F_1 and F_2 do not need individually to be zero. This is generally true of the F_i in equation (93). As a second example, consider a rigid body in space. Here, the constraint of rigidity has already been expressed by reducing the coordinate space to that of six generalized coordinates. These six coordinates (x, y, z, and three angles) can change quite independently of one another. In other words, in equation (93), the six dr_i are arbitrary. Thus, the only way equation (93) can be satisfied is if all six F_i are zero. This means that the rigid body can have no net component of force and no net component of torque acting on it. Of course, this same conclusion was reached earlier (see *Statics*) by less abstract arguments.

LAGRANGE'S AND HAMILTON'S EQUATIONS

Elegant and powerful methods have also been devised for solving dynamic problems with constraints. One of the best known is called Lagrange's equations. The Lagrangian L is defined as $L = T - V$, where T is the kinetic energy and V the potential energy of the system in question. Generally speaking, the potential energy of a system depends on the coordinates of all its particles; this may be written as $V = V(x_1, y_1, z_1, x_2, y_2, z_2, \ldots)$. The kinetic energy generally depends on the velocities, which, using the notation $v_x = dx/dt = \dot{x}$, may be written $T = T(\dot{x}_1, \dot{y}_1, \dot{z}_1, \dot{x}_2, \dot{y}_2, \dot{z}_2, \ldots)$. Thus, a dynamic problem has six dynamic variables for each particle—that is, x, y, z and $\dot{x}$, $\dot{y}$, $\dot{z}$—and the Lagrangian depends on all $6N$ variables if there are N particles.

In many problems, however, the constraints of the problem permit equations to be written relating at least some of these variables. In these cases, the $6N$ related dynamic variables may be reduced to a smaller number of independent generalized coordinates (written symbolically as $q_1, q_2, \ldots q_i, \ldots$) and generalized velocities (written as $\dot{q}_1, \dot{q}_2, \ldots \dot{q}_i, \ldots$), just as, for the rigid body, $3N$ coordinates were reduced to six independent generalized coordinates (each of which has an associated velocity). The Lagrangian, then, may be expressed as a function of all the q_i and $\dot{q}_i$. It is possible, starting from Newton's laws only, to derive Lagrange's equations

Use of generalized coordinates and velocities

$$\frac{d}{dt}\frac{\partial L}{\partial \dot{q}_i} - \frac{\partial L}{\partial q_i} = 0, \tag{94}$$

where the notation $\partial L/\partial q_i$ means differentiate L with respect to q_i only, holding all other variables constant. There is one equation of the form (94) for each of the generalized coordinates q_i (*e.g.*, six equations for a rigid body), and their solutions yield the complete dynamics of the system. The use of generalized coordinates allows many coupled equations of the form (91) to be reduced to fewer, independent equations of the form (94).

There is an even more powerful method called Hamilton's equations. It begins by defining a generalized momentum p_i, which is related to the Lagrangian and the generalized velocity $\dot{q}_i$ by $p_i = \partial L/\partial \dot{q}_i$. A new function, the Hamiltonian, is then defined by $H = \sum_i \dot{q}_i p_i - L$. From this point it is not difficult to derive

$$\dot{q}_i = \frac{\partial H}{\partial p_i} \tag{95}$$

and

$$-\dot{p}_i = \frac{\partial H}{\partial q_i}. \quad (96)$$

These are called Hamilton's equations. There are two of them for each generalized coordinate. They may be used in place of Lagrange's equations, with the advantage that only first derivatives—not second derivatives—are involved.

The Hamiltonian method is particularly important because of its utility in formulating quantum mechanics. However, it is also significant in classical mechanics. If the constraints in the problem do not depend explicitly on time, then it may be shown that $H = T + V$, where T is the kinetic energy and V is the potential energy of the system—*i.e.*, the Hamiltonian is equal to the total energy of the system. Furthermore, if the problem is isotropic (H does not depend on direction in space) and homogeneous (H does not change with uniform translation in space), then Hamilton's equations immediately yield the laws of conservation of angular momentum and linear momentum, respectively. (D.L.G.)

CELESTIAL MECHANICS

Celestial mechanics, in the broadest sense, is the application of classical mechanics to the motion of celestial bodies acted on by any of several types of forces. By far the most important force experienced by these bodies, and much of the time the only important force, is that of their mutual gravitational attraction. But other forces can be important as well, such as atmospheric drag on artificial satellites, the pressure of radiation on dust particles, and even electromagnetic forces on dust particles if they are electrically charged and moving in a magnetic field. The term celestial mechanics is sometimes assumed to refer only to the analysis developed for the motion of point mass particles moving under their mutual gravitational attractions, with emphasis on the general orbital motions of solar system bodies. The term astrodynamics is often used to refer to the celestial mechanics of artificial satellite motion. Dynamic astronomy is a much broader term, which, in addition to celestial mechanics and astrodynamics, is usually interpreted to include all aspects of celestial body motion (*e.g.*, rotation, tidal evolution, mass and mass distribution determinations for stars and galaxies, fluid motions in nebulas, and so forth).

Dynamic astronomy

HISTORICAL BACKGROUND

Early theories. Celestial mechanics has its beginnings in early astronomy in which the motions of the Sun, the Moon, and the five planets visible to the unaided eye—Mercury, Venus, Mars, Jupiter, and Saturn—were observed and analyzed. The word planet is derived from the Greek word for wanderer, and it was natural for some cultures to elevate these objects moving against the fixed background of the sky to the status of gods; this status survives in some sense today in astrology, where the positions of the planets and Sun are thought to somehow influence the lives of individuals on Earth. The divine status of the planets and their supposed influence on human activities may have been the primary motivation for careful, continued observations of planetary motions and for the development of elaborate schemes for predicting their positions in the future.

The Greek astronomer Ptolemy (who lived in Alexandria about AD 140) proposed a system of planetary motion in which the Earth was fixed at the centre and all the planets, the Moon, and the Sun orbited around it. As seen by an observer on the Earth, the planets move across the sky at a variable rate. They even reverse their direction of motion occasionally but resume the dominant direction of motion after a while. To describe this variable motion, Ptolemy assumed that the planets revolved around small circles called epicycles at a uniform rate while the centre of the epicyclic circle orbited the Earth on a large circle called a deferent. Other variations in the motion were accounted for by offsetting the centres of the deferent for each planet from the Earth by a short distance. By choosing the combination of speeds and distances appropriately, Ptolemy was able to predict the motions of the planets with considerable accuracy. His scheme was adopted as absolute dogma and survived more than 1,000 years until the time of Copernicus.

Nicolaus Copernicus assumed that the Earth was just another planet that orbited the Sun along with the other planets. He showed that this heliocentric (centred on the Sun) model was consistent with all observations and that it was far simpler than Ptolemy's scheme. His belief that planetary motion had to be a combination of uniform circular motions forced him to include a series of epicycles to match the motions in the noncircular orbits. The epicycles were like terms in the Fourier series that are used to represent planetary motions today. (A Fourier series is an infinite sum of periodic terms that oscillate between positive and negative values in a smooth way, where the frequency of oscillation changes from term to term. They represent better and better approximations to other functions as more and more terms are kept.) Copernicus also determined the relative scale of his heliocentric solar system, with results that are remarkably close to the modern determination.

Copernicus' heliocentric model

Tycho Brahe (1546–1601), who was born three years after Copernicus' death and three years after the publication of the latter's heliocentric model of the solar system, still embraced a geocentric model, but he had only the Sun and the Moon orbiting the Earth and all the other planets orbiting the Sun. Although this model is mathematically equivalent to the heliocentric model of Copernicus, it represents an unnecessary complication and is physically incorrect. Tycho's greatest contribution was the more than 20 years of celestial observations he collected; his measurements of the positions of the planets and stars had an unprecedented accuracy of approximately 2 arc minutes. (An arc minute is $^1/_{60}$ of a degree.)

Kepler's laws of planetary motion. Tycho's observations were inherited by Johannes Kepler (1571–1630), who was employed by Tycho shortly before the latter's death. From these precise positions of the planets at correspondingly accurate times, Kepler empirically determined his famous three laws describing planetary motion: (1) the orbits of the planets are ellipses with the Sun at one focus; (2) the radial line from the Sun to the planet sweeps out equal areas in equal times; and (3) the ratio of the squares of the periods of revolution around the Sun of any two planets equal the ratio of the cubes of the semimajor axes of their respective orbital ellipses.

An ellipse (Figure 27) is a plane curve defined such that the sum of the distances from any point G on the ellipse to two fixed points (S and S' in Figure 27) is constant. The two points S and S' are called foci, and the straight line on which these points lie between the extremes of the ellipse at A and P is referred to as the major axis of the ellipse. Hence, $GS + GS' = AP = 2a$ in Figure 27, where a is the semimajor axis of the ellipse. A focus is separated from the centre C of the ellipse by the fractional part of the semimajor axis given by the product ae, where $e < 1$ is called the eccentricity. Thus, $e = 0$ corresponds to a circle. If the Sun is at the focus S of the ellipse, the point P at which the planet is closest to the Sun is called the perihelion, and the most distant point in the orbit A is the aphelion. The term helion refers specifically to the Sun as the primary body about which the planet is orbiting. As the points P and A are also called apses, periapse and apoapse are often used to designate the corresponding points in an orbit about any primary body, although more specific terms, such as perigee and apogee for the Earth, are often used to indicate the primary body. If G is the instantaneous location of a planet in its orbit, the angle f, called the true anomaly, locates this point relative to the perihelion P with the Sun (or focus S) as the origin, or vertex, of the angle. The angle u, called the eccentric anomaly, also locates G relative to P but with the centre

of the ellipse as the origin rather than the focus S. An angle called the mean anomaly l (not shown in Figure 27) is also measured from P with S as the origin; it is defined to increase uniformly with time and to equal the true anomaly f at perihelion and aphelion.

Law of equal areas

Kepler's second law is also illustrated in Figure 27. If the time required for the planet to move from P to F is the same as that to move from D to E, the areas of the two shaded regions will be equal according to the second law. The validity of the second law means a planet must have a higher than average velocity near perihelion and a lower than average velocity near aphelion. The angular velocity (rate of change of the angle f) must vary around the orbit in a similar way. The average angular velocity, called the mean motion, is the rate of change of the mean anomaly l defined above.

The third law can be used to determine the distance of a planet from the Sun if one knows its orbital period, or vice versa. In particular, if time is measured in years and distance in units of the semimajor axis of the Earth's orbit (*i.e.*, the mean distance of the Earth to the Sun, known as an astronomical unit, or AU), the third law can be written $\tau^2 = a^3$, where τ is the orbital period.

Newton's laws of motion. The empirical laws of Kepler describe planetary motion, but Kepler made no attempt to define or constrain the underlying physical processes governing the motion. It was Isaac Newton who accomplished that feat in the late 17th century. Newton defined momentum as being proportional to velocity with the constant of proportionality being defined as mass. (As described earlier, momentum is a vector quantity in the sense that the direction of motion as well as the magnitude is included in the definition.) Newton then defined force (also a vector quantity) in terms of its effect on moving objects and in the process formulated his three laws of motion: (1) The momentum of an object is constant unless an outside force acts on the object; this means that any object either remains at rest or continues uniform motion in a straight line unless acted on by a force. (2) The time rate of change of the momentum of an object is equal to the force acting on the object. (3) For every action (force) there is an equal and opposite reaction (force). The first law is seen to be a special case of the second law. Galileo, the great Italian contemporary of Kepler who adopted the Copernican point of view and promoted it vigorously, anticipated Newton's first two laws with his experiments in mechanics. But it was Newton who defined them precisely, established the basis of classical mechanics, and set the stage for its application as celestial mechanics to the motions of bodies in space.

According to the second law, a force must be acting on a planet to cause its path to curve toward the Sun. Newton and others noted that the acceleration of a body in uniform circular motion must be directed toward the centre of the circle; furthermore, if several objects were in circular motion around the same centre at various separations r and their periods of revolution varied as $r^{3/2}$, as Kepler's third law indicated for the planets, then the acceleration—and thus, by Newton's second law, the force as well—must vary as $1/r^2$. By assuming this attractive force between point masses, Newton showed that a spherically symmetric mass distribution attracted a second body outside the sphere as if all the spherically distributed mass were contained in a point at the centre of the sphere. Thus the attraction of the planets by the Sun was the same as the gravitational force attracting objects to the Earth. Newton further concluded that the force of attraction between two massive bodies was proportional to the inverse square of their separation and to the product of their masses, known as the law of universal gravitation. Kepler's laws are derivable from Newton's laws of motion with a central force of gravity varying as $1/r^2$ from a fixed point, and Newton's law of gravity is derivable from Kepler's laws if one assumes Newton's laws of motion.

In addition to formulating the laws of motion and of gravity, Newton also showed that a point mass moving about a fixed centre of force, which varies as the inverse square of the distance away from the centre, follows an elliptical path if the initial velocity is not too large, a hyperbolic path for high initial velocities, and a parabolic path for intermediate velocities. In other words, a sequence of orbits in Figure 27 with the perihelion distance SP fixed but with the velocity at P increasing from orbit to orbit is characterized by a corresponding increase in the orbital eccentricity e from orbit to orbit such that $e < 1$ for bound elliptical orbits, $e = 1$ for a parabolic orbit, and $e > 1$ for a hyperbolic orbit. Many comets have nearly parabolic orbits for their first pass into the inner solar system, whereas spacecraft may have nearly hyperbolic orbits relative to a planet they are flying by while they are close to the planet.

Orbital eccentricity

Throughout history, the motion of the planets in the solar system has served as a laboratory to constrain and guide the development of celestial mechanics in particular and classical mechanics in general. In modern times, increasingly precise observations of celestial bodies have been matched by increasingly precise predictions for future positions—a combination that became a test for Newton's law of gravitation itself. Although the lunar motion (within observational errors) seemed consistent with a gravitational attraction between point masses that decreased exactly as $1/r^2$, this law of gravitation was ultimately shown to be an approximation of the more complete description of gravity given by the theory of general relativity. Similarly, a discrepancy of roughly 40 arc seconds per century between the observed rate of advance of Mercury's perihelion and that predicted by planetary perturbations with Newtonian gravity is almost precisely accounted for with Einstein's general theory of relativity. That this small discrepancy could be confidently asserted as real was a triumph of quantitative celestial mechanics.

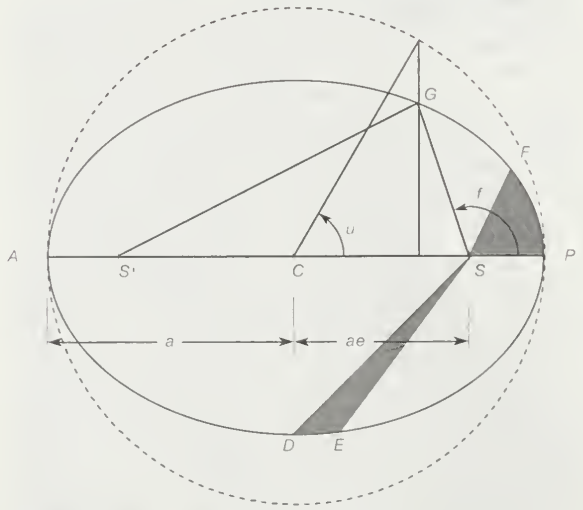

Figure 27: The orbital elements *a* (the semimajor axis) and *e* (the eccentricity) characterize an elliptical orbit; the angles *f* and *u* allow location of the position of a planet on the orbit relative to the point *P*; the shaded areas illustrate Kepler's second law (see text).

PERTURBATIONS AND PROBLEMS OF TWO BODIES

The approximate nature of Kepler's laws. The constraints placed on the force for Kepler's laws to be derivable from Newton's laws were that the force must be directed toward a central fixed point and that the force must decrease as the inverse square of the distance. In actuality, however, the Sun, which serves as the source of the major force, is not fixed but experiences small accelerations because of the planets, in accordance with Newton's second and third laws. Furthermore, the planets attract one another, so that the total force on a planet is not just that due to the Sun; other planets perturb the elliptical motion that would have occurred for a particular planet if that planet had been the only one orbiting an isolated Sun. Kepler's laws therefore are only approximate. The motion of the Sun itself means that, even when the attractions by other planets are neglected, Kepler's third law must be replaced by $(M + m_i)\tau^2 \propto a^3$, where m_i is one of the planetary masses and M is the Sun's mass. That Kepler's laws are such good approximations to the actual planetary motions results from the fact that all the planetary masses are very

small compared to that of the Sun. The perturbations of the elliptic motion are therefore small, and the coefficient $M + m_i \approx M$ for all the planetary masses m_i means that Kepler's third law is very close to being true.

Newton's second law for a particular mass is a second-order differential equation that must be solved for whatever forces may act on the body if its position as a function of time is to be deduced. The exact solution of this equation, which resulted in a derived trajectory that was an ellipse, parabola, or hyperbola, depended on the assumption that there were only two point particles interacting by the inverse square force. Hence, this "gravitational two-body problem" has an exact solution that reproduces Kepler's laws. If one or more additional bodies also interact with the original pair through their mutual gravitational interactions, no exact solution for the differential equations of motion of any of the bodies involved can be obtained. As was noted above, however, the motion of a planet is almost elliptical, since all masses involved are small compared to the Sun. It is then convenient to treat the motion of a particular planet as slightly perturbed elliptical motion and to determine the changes in the parameters of the ellipse that result from the small forces as time progresses. It is the elaborate developments of various perturbation theories and their applications to approximate the exact motions of celestial bodies that has occupied celestial mechanicians since Newton's time.

Orbital elements

Perturbations of elliptical motion. So far the following orbital parameters, or elements, have been used to describe elliptical motion: the orbital semimajor axis a; the orbital eccentricity e, and, to specify position in the orbit relative to the perihelion, either the true anomaly f, the eccentric anomaly u, or the mean anomaly l. Three more orbital elements are necessary to orient the ellipse in space, since that orientation will change because of the perturbations. The most commonly chosen of these additional parameters are illustrated in Figure 28, where the reference plane is chosen arbitrarily to be the plane of the ecliptic, which is the plane of the Earth's orbit defined by the path of the Sun on the sky. (For motion of a near-Earth artificial satellite, the most convenient reference plane would be that of the Earth's Equator.) Angle i is the inclination of the orbital plane to the reference plane. The line of nodes is the intersection of the orbit plane with the reference plane, and the ascending node is that point where the planet travels from below the reference plane (south) to above the reference plane (north). The ascending node is described by its angular position measured from a reference point on the ecliptic plane, such as the vernal equinox; the angle Ω is called the longitude of the ascending node. Angle ω (called the argument of perihelion) is the angular distance from the ascending node to the perihelion measured in the orbit plane.

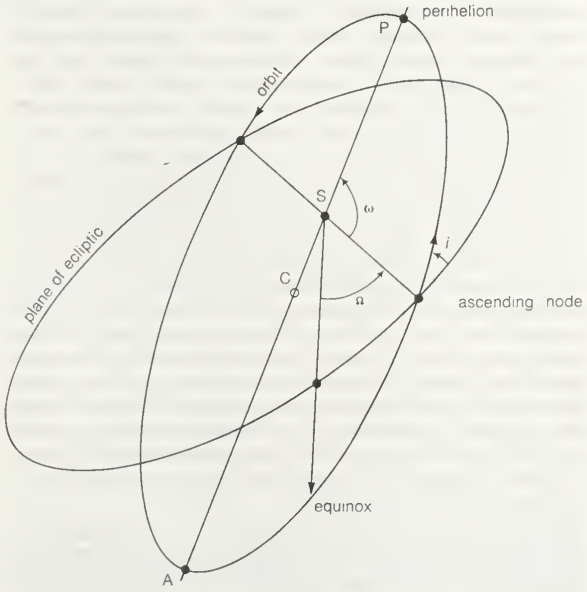

Figure 28: Orbital elements Ω, ω, and i orienting the ellipse.

For the two-body problem, all the orbital parameters a, e, i, Ω, and ω are constants. A sixth constant T, the time of perihelion passage (*i.e.*, any date at which the object in orbit was known to be at perihelion), may be used to replace f, u, or l, and the position of the planet in its fixed elliptic orbit can be determined uniquely at subsequent times. These six constants are determined uniquely by the six initial conditions of three components of the position vector and three components of the velocity vector relative to a coordinate system that is fixed with respect to the reference plane. When small perturbations are taken into account, it is convenient to consider the orbit as an instantaneous ellipse whose parameters are defined by the instantaneous values of the position and velocity vectors, since for small perturbations the orbit is approximately an ellipse. In fact, however, perturbations cause the six formerly constant parameters to vary slowly, and the instantaneous perturbed orbit is called an osculating ellipse; that is, the osculating ellipse is that elliptical orbit that would be assumed by the body if all the perturbing forces were suddenly turned off.

First-order differential equations describing the variation of the six orbital parameters can be constructed for each planet or other celestial body from the second-order differential equations that result by equating the mass times the acceleration of a body to the sum of all the forces acting on the body (Newton's second law). These equations are sometimes called the Lagrange planetary equations after their derivation by the great Italian-French mathematician Joseph-Louis Lagrange (1736–1813). As long as the forces are conservative and do not depend on the velocities—*i.e.*, there is no loss of mechanical energy through such processes as friction—they can be derived from partial derivatives of a function of the spatial coordinates only, called the potential energy, whose magnitude depends on the relative separations of the masses.

In the case where all the forces are derivable from such potential energy, the total energy of a system of any number of particles—*i.e.* the kinetic energy plus the potential energy—is constant. The kinetic energy of a single particle is one-half its mass times the square of its velocity, and the total kinetic energy is the sum of such expressions for all the particles being considered. The conservation of energy principle is thus expressed by an equation relating the velocities of all the masses to their positions at any time. The partial derivatives of the potential energy with respect to spatial coordinates are transformed into particle derivatives of a disturbing function with respect to the orbital elements in the Lagrange equations, where the disturbing function vanishes if all bodies perturbing the elliptic motion are removed. Like Newton's equations of motion, Lagrange's differential equations are exact, but they can be solved only numerically on a computer or analytically by successive approximations. In the latter process, the disturbing function is represented by a Fourier series, with convergence of the series (successive decrease in size and importance of the terms) depending on the size of the orbital eccentricities and inclinations. Clever changes of variables and other mathematical tricks are used to increase the time span over which the solutions (also represented by series) are good approximations to the real motion. These series solutions usually diverge, but they still represent the actual motions remarkably well for limited periods of time. One of the major triumphs of celestial mechanics using these perturbation techniques was the discovery of Neptune in 1846 from its perturbations of the motion of Uranus.

Disturbing function

Examples of perturbations. Some of the variations in the orbital parameters caused by perturbations can be understood in simple terms. The lunar orbit is inclined to the ecliptic plane by about 5°, and the longitude of its ascending node on the ecliptic plane (Ω in Figure 28) is observed to regress (Ω decreasing) a complete revolution in 18.61 years. The Sun is the dominant cause of this regression of the lunar node. When the Moon is closer to the Sun than the Earth, the Sun accelerates the Moon slightly more than it accelerates the Earth. This difference in the accelerations is what perturbs the lunar motion around the Earth. The Moon does not fly off in this situation since

the acceleration of the Moon toward the Earth is much larger than the difference between the Sun's accelerations of the Earth and the Moon.

The Sun, of course, is always in the ecliptic plane, since its apparent path among the stars defines the plane. This means that the perturbing acceleration just defined will always be pointed slightly toward the ecliptic plane whenever the Moon is below or above this plane in its orbital motion about the Earth. This tendency to pull the Moon toward the ecliptic plane means that the Moon will cross the plane on each half orbit at a longitude that is slightly smaller than the longitude at which it would have crossed if the Sun had not been there. Thus, the line of nodes will have regressed. The instantaneous rate at which the node regresses varies as the geometry changes during the Moon's motion around the Earth, and during the Earth-Moon system's motion around the Sun, but there is always a net regression. Such a change that is always in the same direction as time increases is called a secular perturbation. Superposed on the secular perturbation of the longitude of the node are periodic perturbations (periodically changing their direction), which are revealed by the fact that the rate of secular regression of the node is not constant in time. The Sun causes a secular increase in the longitude of the lunar perigee ($\Omega + \omega$ in Figure 28) of one complete revolution in 8.85 years, as well as periodic perturbations in the inclination, eccentricity, and mean motion.

For near-Earth artificial satellites, the deviation of the Earth's mass distribution from spherical symmetry is the dominant cause of the perturbations from pure elliptic motion. The most important deviation is the equatorial bulge of the Earth due to its rotation. If, for example, the Earth were a sphere with a ring of mass around its Equator, the ring would give to a satellite whose orbit is inclined to the Equator a component of acceleration toward the Equator plane whenever the satellite was above or below this plane. By an argument similar to that for the Moon acted on by the Sun, this acceleration would cause the line of nodes of a close satellite orbit to regress a little more than 5° per day.

As a final example, the distribution of continents and oceans and the varying mass densities in the Earth's mantle (the layer underlying the crust) lead to a slight deviation of the Earth's gravitational force field from axial symmetry. Usually this causes only short-period perturbations of low amplitude for near-Earth satellites. However, communications or weather satellites that are meant to maintain a fixed longitude over the Equator (*i.e.*, geostationary satellites, which orbit synchronously with the Earth's rotation) are destabilized by this deviation except at two longitudes. If the axial asymmetry is represented by a slightly elliptical Equator, the difference between the major and minor axis of the ellipse is about 64 metres, with the major axis located about 35° W. A satellite at a position slightly ahead of the long axis of the elliptical Equator will experience a component of acceleration opposite its direction of orbital motion (as if a large mountain were pulling it back). This acceleration makes the satellite fall closer to the Earth and increases its mean motion, causing it to drift further ahead of the axial bulge on the Equator. If the satellite is slightly behind the axial bulge, it experiences an acceleration in the direction of its motion. This makes the satellite move away from the Earth with a decrease in its mean motion, so that it will drift further behind the axial bulge. The synchronous Earth satellites are thus repelled from the long axis of the equatorial ellipse and attracted to the short axis, and compensating accelerations, usually from onboard jets, are required to stabilize a satellite at any longitude other than the two corresponding to the ends of the short axis of the axial bulge. (The jets are actually required for any longitude, as they must also compensate for other perturbations such as radiation pressure.)

Synchronous Earth satellites

THE THREE-BODY PROBLEM

The inclusion of solar perturbations of the motion of the Moon results in a "three-body problem" (Earth-Moon-Sun), which is the simplest complication of the completely solvable two-body problem discussed above. When the Earth, Moon, and Sun are considered to be point masses, this particular three-body problem is called "the main problem of the lunar theory," which has been studied extensively with a variety of methods beginning with Newton. Although the three-body problem has no complete analytic solution in closed form, various series solutions by successive approximations achieve such accuracy that complete theories of the lunar motion must include the effects of the nonspherical mass distributions of both the Earth and the Moon as well as the effects of the planets if the precision of the predicted positions is to approach that of the observations. Most of the schemes for the main problem are partially numerical and therefore apply only to the lunar motion. An exception is the completely analytic work of the French astronomer Charles-Eugène Delaunay (1816–72), who exploited and developed the most elegant techniques of classical mechanics pioneered by his contemporary, the Irish astronomer and mathematician William R. Hamilton (1805–65). Delaunay could predict the position of the Moon to within its own diameter over a 20-year time span. Since his development was entirely analytic, the work was applicable to the motions of satellites about other planets where the series expansions converged much more rapidly than they did for the application to the lunar motion.

Influence on classical mechanics

Delaunay's work on the lunar theory demonstrates some of the influence that celestial mechanics has had on the development of the techniques of classical mechanics. This close link between the development of classical mechanics and its application to celestial mechanics was probably no better demonstrated than in the work of the French mathematician Henri Poincaré (1854–1912). Poincaré, along with other great mathematicians such as George D. Birkhoff (1884–1944), Aurel Wintner (1903–58), and Andrey N. Kolmogorov (1903–87), placed celestial mechanics on a more sound mathematical basis and was less concerned with quantitatively accurate prediction of celestial body motion. Poincaré demonstrated that the series solutions in use in celestial mechanics for so long generally did not converge but that they could give accurate descriptions of the motion for significant periods of time in truncated form. The elaborate theoretical developments in celestial and classical mechanics have received more attention recently with the realization that a large class of motions are of an irregular or chaotic nature and require fundamentally different approaches for their description.

The restricted three-body problem. The simplest form of the three-body problem is called the restricted three-body problem, in which a particle of infinitesimal mass moves in the gravitational field of two massive bodies orbiting according to the exact solution of the two-body problem. (The particle with infinitesimal mass, sometimes called a massless particle, does not perturb the motions of the two massive bodies.) There is an enormous literature devoted to this problem, including both analytic and numerical developments. The analytic work was devoted mostly to the circular, planar restricted three-body problem, where all particles are confined to a plane and the two finite masses are in circular orbits around their centre of mass (a point on the line between the two masses that is closer to the more massive). Numerical developments allowed consideration of the more general problem.

In the circular problem, the two finite masses are fixed in a coordinate system rotating at the orbital angular velocity, with the origin (axis of rotation) at the centre of mass of the two bodies. Lagrange showed that in this rotating frame there were five stationary points at which the massless particle would remain fixed if placed there. There are three such points lying on the line connecting the two finite masses: one between the masses and one outside each of the masses. The other two stationary points, called the triangular points, are located equidistant from the two finite masses at a distance equal to the finite mass separation. The two masses and the triangular stationary points are thus located at the vertices of equilateral triangles in the plane of the circular orbit.

There is a constant of the motion in the rotating frame that leads to an equation relating the velocity of the massless particle in this frame to its position. For given values of this constant it is possible to construct curves in the

Zero-velocity curves

plane on which the velocity vanishes. If such a zero-velocity curve is closed, the particle cannot escape from the interior of the closed zero-velocity curve if placed there with the constant of the motion equal to the value used to construct the curve. These zero-velocity curves can be used to show that the three collinear stationary points are all unstable in the sense that, if the particle is placed at one of these points, the slightest perturbation will cause it to move far away. The triangular points are stable if the ratio of the finite masses is less than 0.04, and the particle would execute small oscillations around one of the triangular points if it were pushed slightly away. Since the mass ratio of Jupiter to the Sun is about 0.001, the stability criterion is satisfied, and Lagrange predicted the presence of the Trojan asteroids at the triangular points of the Sun-Jupiter system 134 years before they were observed. Of course, the stability of the triangular points must also depend on the perturbations by any other bodies. Such perturbations are sufficiently small not to destabilize the Trojan asteroids. Single Trojan-like bodies have also been found orbiting at leading and trailing triangular points in the orbit of Saturn's satellite Tethys, at the leading triangular point in the orbit of another Saturnian satellite, Dione, and at the trailing point in the orbit of Mars.

Orbital resonances. There are stable configurations in the restricted three-body problem that are not stationary in the rotating frame. If, for example, Jupiter and the Sun are the two massive bodies, these stable configurations occur when the mean motions of Jupiter and the small particle—here an asteroid—are near a ratio of small integers. The orbital mean motions are then said to be nearly commensurate, and an asteroid that is trapped near such a mean motion commensurability is said to be in an orbital resonance with Jupiter. For example, the Trojan asteroids librate (oscillate) around the 1:1 orbital resonance (*i.e.*, the orbital period of Jupiter is in a 1:1 ratio with the orbital period of the Trojan asteroids); the asteroid Thule librates around the 4:3 orbital resonance; and several asteroids in the Hilda group librate around the 3:2 orbital resonance. There are several such stable orbital resonances among the satellites of the major planets and one involving the planets Pluto and Neptune. The analysis based on the restricted three-body problem cannot be used for the satellite resonances, however, except for the 4:3 resonance between Saturn's satellites Titan and Hyperion, since the participants in the satellite resonances usually have comparable masses.

Although the asteroid Griqua librates around the 2:1 resonance with Jupiter, and Alinda librates around the 3:1 resonance, the orbital commensurabilities 2:1, 7:3, 5:2, and 3:1 are characterized by an absence of asteroids in an otherwise rather highly populated, uniform distribution spanning all of the commensurabilities. These are the Kirkwood gaps in the distribution of asteroids, and the recent understanding of their creation and maintenance has introduced into celestial mechanics an entirely new concept of irregular, or chaotic, orbits in a system whose equations of motion are entirely deterministic.

Kirkwood gaps

Chaotic orbits. The French astronomer Michel Hénon and the American astronomer Carl Heiles discovered that when a system exhibiting periodic motion, such as a pendulum, is perturbed by an external force that is also periodic, some initial conditions lead to motions where the state of the system becomes essentially unpredictable (within some range of system states) at some time in the future, whereas initial conditions within some other set produce quasiperiodic or predictable behaviour. The unpredictable behaviour is called chaotic, and initial conditions that produce it are said to lie in a chaotic zone. If the chaotic zone is bounded, in the sense that only limited ranges of initial values of the variables describing the motion lead to chaotic behaviour, the uncertainty in the state of the system in the future is limited by the extent of the chaotic zone; that is, values of the variables in the distant future are completely uncertain only within those ranges of values within the chaotic zone. This complete uncertainty within the zone means the system will eventually come arbitrarily close to any set of values of the variables within the zone if given sufficient time. Chaotic orbits were first realized in the asteroid belt.

A periodic term in the expansion of the disturbing function for a typical asteroid orbit becomes more important in influencing the motion of the asteroid if the frequency with which it changes sign is very small and its coefficient is relatively large. For asteroids orbiting near a mean motion commensurability with Jupiter, there are generally several terms in the disturbing function with large coefficients and small frequencies that are close but not identical. These "resonant" terms often dominate the perturbations of the asteroid motion so much that all the higher-frequency terms can be neglected in determining a first approximation to the perturbed motion. This neglect is equivalent to averaging the higher-frequency terms to zero; the low-frequency terms change only slightly during the averaging. If one of the frequencies vanishes on the average, the periodic term becomes nearly constant, or secular, and the asteroid is locked into an exact orbital resonance near the particular mean motion commensurability. The mean motions are not exactly commensurate in such a resonance, however, since the motion of the asteroid orbital node or perihelion is always involved (except for the 1:1 Trojan resonances).

Approximating asteroid motion

For example, for the 3:1 commensurability, the angle $\theta = \lambda_A - 3\lambda_J + \varpi_A$ is the argument of one of the important periodic terms whose variation can vanish (zero frequency). Here $\lambda = \Omega + \omega + l$ is the mean longitude, the subscripts A and J refer to the asteroid and Jupiter, respectively, and $\varpi = \Omega + \omega$ is the longitude of perihelion (see Figure 28). Within resonance, the angle θ librates, or oscillates, around a constant value as would a pendulum around its equilibrium position at the bottom of its swing. The larger the amplitude of the equivalent pendulum, the larger its velocity at the bottom of its swing. If the velocity of the pendulum at the bottom of its swing, or, equivalently, the maximum rate of change of the angle θ, is sufficiently high, the pendulum will swing over the top of its support and be in a state of rotation instead of libration. The maximum value of the rate of change of θ for which θ remains an angle of libration (periodically reversing its variation) instead of one of rotation (increasing or decreasing monotonically) is defined as the half-width of the resonance.

Another term with nearly zero frequency when the asteroid is near the 3:1 commensurability has the argument $\theta' = \lambda_A - \lambda_J + 2\varpi_J$. The substitution of the longitude of Jupiter's perihelion for that of the asteroid means that the rates of change of θ and θ' will be slightly different. As the resonances are not separated much in frequency, there may exist values of the mean motion of the asteroid where both θ and θ' would be angles of libration if either resonance existed in the absence of the other. The resonances are said to overlap in this case, and the attempt by the system to librate simultaneously about both resonances for some initial conditions leads to chaotic orbital behaviour. The important characteristic of the chaotic zone for asteroid motion near a mean motion commensurability with Jupiter is that it includes a region where the asteroid's orbital eccentricity is large. During the variation of the elements over the entire chaotic zone as time increases, large eccentricities must occasionally be reached. For asteroids near the 3:1 commensurability with Jupiter, the orbit then crosses that of Mars, whose gravitational interaction in a close encounter can remove the asteroid from the 3:1 zone.

By numerically integrating many orbits whose initial conditions spanned the 3:1 Kirkwood gap region in the asteroid belt, Jack Wisdom, an American dynamicist who developed a powerful means of analyzing chaotic motions, found that the chaotic zone around this gap precisely matched the physical extent of the gap. There are no observable asteroids with orbits within the chaotic zone, but there are many just outside extremes of the zone. Preliminary work has indicated that the other Kirkwood gaps can be similarly accounted for. The realization that orbits governed by Newton's laws of motion and gravitation could have chaotic properties and that such properties could solve a long-standing problem in the celestial mechanics of the solar system is a major breakthrough in the subject.

Chaotic zones

THE *n*-BODY PROBLEM

The general problem of n bodies, where n is greater than three, has been attacked vigorously with numerical techniques on powerful computers. Celestial mechanics in the solar system is ultimately an n-body problem, but the special configurations and relative smallness of the perturbations have allowed quite accurate descriptions of motions (valid for limited time periods) with various approximations and procedures without any attempt to solve the complete problem of n bodies. Examples are the restricted three-body problem to determine the effect of Jupiter's perturbations of the asteroids and the use of successive approximations of series solutions to sequentially add the effects of smaller and smaller perturbations for the motion of the Moon. In the general n-body problem, all bodies have arbitrary masses, initial velocities, and positions; the bodies interact through Newton's law of gravitation, and one attempts to determine the subsequent motion of all the bodies. Many numerical solutions for the motion of quite large numbers of gravitating particles have been successfully completed where the precise motion of individual particles is usually less important than the statistical behaviour of the group.

Numerical solutions. Numerical solutions of the exact equations of motion for n bodies can be formulated. Each body is subject to the gravitational attraction of all the others, and it may be subject to other forces as well. It is relatively easy to write the expression for the instantaneous acceleration (equation of motion) of each body if the position of all the other bodies is known, and expressions for all the other forces can be written (as they can for gravitational forces) in terms of the relative positions of the particles and other defining characteristics of the particle and its environment. Each particle is allowed to move under its instantaneous acceleration for a short time step. Its velocity and position are thereby changed, and the new values of the variables are used to calculate the acceleration for the next time step, and so forth. Of course, the real position and velocity of the particle after each time step will differ from the calculated values by errors of two types. One type results from the fact that the acceleration is not really constant over the time step, and the other from the rounding off or truncation of the numbers at every step of the calculation. The first type of error is decreased by taking shorter time steps. But this means more numerical operations must be carried out over a given span of time, and this increases the round-off error for a given precision of the numbers being carried in the calculation. The design of numerical algorithms, as well as the choice of precisions and step sizes that maximize the speed of the calculation while keeping the errors within reasonable bounds, is almost an art form developed by extensive experience and ingenuity. For example, a scheme exists for extrapolating the step size to zero in order to find the change in the variables over a relatively short time span, thereby minimizing the accumulation of error from this source. If the total energy of the system is theoretically conserved, its evaluation for values of the variables at the beginning and end of a calculation is a measure of the errors that have accumulated.

Stability of the solar system

The motion of the nine planets of the solar system over time scales approaching its 4.6-billion-year age is a classic n-body problem, where $n = 10$ with the Sun included. The question of whether or not the solar system is ultimately stable—whether the current configuration of the planets will be maintained indefinitely under their mutual perturbations, or whether one or another planet will eventually be lost from the system or otherwise have its orbit drastically altered—is a long-standing one that might someday be answered through numerical calculation. The interplay of orbital resonances and chaotic orbits discussed above can be investigated numerically, and this interplay may be crucial in determining the stability of the solar system. Already it appears that the parameters defining the orbits of several planets, especially that of Pluto, vary over narrow chaotic zones, but whether or not this chaos can lead to instability if given enough time is still uncertain.

If accelerations are determined by summing all the pairwise interactions for the n particles, the computer time per time step increases as n^2. Practical computations for the direct calculation of the interactions between all the particles are thereby limited to $n < 10{,}000$. Therefore, for larger values of n, schemes are used where a particle is assumed to move in the force field of the remaining particles approximated by that due to a continuum mass distribution, or a "tree structure" is used where the effects of nearby particles are considered individually while larger and larger groups of particles are considered collectively as their distances increase. These later schemes have the capability of calculating the evolution of a very large system of particles using a reasonable amount of computer time with reasonable approximation. Values of n near 100,000 have been used in calculations determining the evolution of galaxies of stars. Also, the consequences for distribution of stars when two galaxies closely approach one another or even collide has been determined. Even calculations of the n-body problem where n changes with time have been completed in the study of the accumulation of larger bodies from smaller bodies via collisions in the process of the formation of the planets.

In all n-body calculations, very close approaches of two particles can result in accelerations so large and so rapidly changing that large errors are introduced or the calculation completely diverges. Accuracy can sometimes be maintained in such a close approach, but only at the expense of requiring very short time steps, which drastically slows the calculation. When n is small, as in some solar system calculations where two-body orbits still dominate, close approaches are sometimes handled by a change to a set of variables, usually involving the eccentric anomaly u, that vary much less rapidly during the encounter. In this process, called regularization, the encounter is traversed in less computer time while preserving reasonable accuracy. This process is impractical when n is large, so accelerations are usually artificially bounded on close approaches to prevent instabilities in the numerical calculation and to prevent slowing the calculation. For example, if several sets of particles were trapped in stable, close binary orbits, the very short time steps required to follow this rapid motion would bring the calculation to a virtual standstill, and such binary motion is not important in the overall evolution of, say, a galaxy of stars.

Regularization

Algebraic maps. In numerical calculations for conservative systems with modest values of n over long time spans, such as those seeking a determination of the stability of the solar system, the direct solution of the differential equations governing the motions requires excessive time on any computer and accumulates excessive round-off error in the process. Excessive time also is required to explore thoroughly a complete range of orbital parameters in numerical experiments in order to determine the extent of chaotic zones in various configurations (*e.g.*, those in the asteroid belt near orbital mean motion commensurabilities with Jupiter). A solution to this problem is the use of an algebraic map, which maps the space of system variables onto itself in such a way that the values of all the variables at one instant of time are expressed by algebraic relations in terms of the values of the variables at a fixed time in the past. The values at the next time step are determined by applying the same map to the values just obtained, and so on. The map is constructed by assuming that the motions of all the bodies are unperturbed for a given short time but are periodically "kicked" by the perturbing forces for only an instant. The continuous perturbations are thus replaced by periodic impulses. The values of the variables are "mapped" from one time step to the next by the fact that the unperturbed part of the motion is available from the exact solution of the two-body problem, and it is easy to solve the equations with all the perturbations over the short time of the impulse. Although this approximation does not produce exactly the same values of all the variables at some time in the future as those produced by a numerical solution of the differential equations starting with the same initial conditions, the qualitative behaviour is indistinguishable over long time periods. As computers can perform the algebraic calculations as much as 1,000 times faster than they can solve the corresponding differential equations, the computational time savings are

enormous and problems otherwise impossible to explore become tractable.

TIDAL EVOLUTION

This discussion has so far treated the celestial mechanics of bodies accelerated by conservative forces (total energy being conserved), including perturbations of elliptic motion by nonspherical mass distributions of finite-size bodies. However, the gravitational field of one body in close orbit about another will tidally distort the shape of the other body. Dissipation of part of the energy stored in these tidal distortions leads to a coupling that causes secular changes (always in the same direction) in the orbit and in the spins of both bodies. Since tidal dissipation accounts for the current spin states of several planets, the spin states of most of the planetary satellites and some of their orbital configurations, and the spins and orbits of close binary stars, it is appropriate that tides and their consequences be included in this discussion.

Tidal deformations of the Earth

The twice-daily high and low tides in the ocean are known by all who have lived near a coast. Few are aware, however, that the solid body of the Earth also experiences twice-daily tides with a maximum amplitude of about 30 centimetres. George Howard Darwin (1845–1912), the second son of Charles Darwin, the naturalist, was an astronomer-geophysicist who understood quantitatively the generation of the tides in the gravitational fields of tide-raising bodies, which are primarily the Moon and Sun for the Earth; he pointed out that the dissipation of tidal energy resulted in a slowing of the Earth's rotation while the Moon's orbit was gradually expanded. That any mass raises a tide on every other mass within its gravitational field follows from the fact that the gravitational force between two masses decreases as the inverse square of the distance between them.

In Figure 29, the accelerations due to mass m_s of three mass elements in the spherical mass m_p are proportional to the length of the arrows attached to each element. The element nearest m_s is accelerated more than the element at the centre of m_p and tends to leave the centre element behind; the element at the centre of m_p is accelerated more than the element farthest from m_s, and the latter tends to be left further behind. The point of view of a fictitious observer at the centre of m_p can be realized by subtracting the acceleration of the central mass element from that of each of the other two mass elements. If the mass elements were free, this observer would see the two extreme mass elements being accelerated in opposite directions away from his position at the centre, as illustrated in Figure 29B.

But the mass elements are not free; they are gravitationally attracted to one another and to the remaining mass in m_p. The gravitational acceleration of the mass elements on the surface of m_p toward the centre of m_p far exceeds

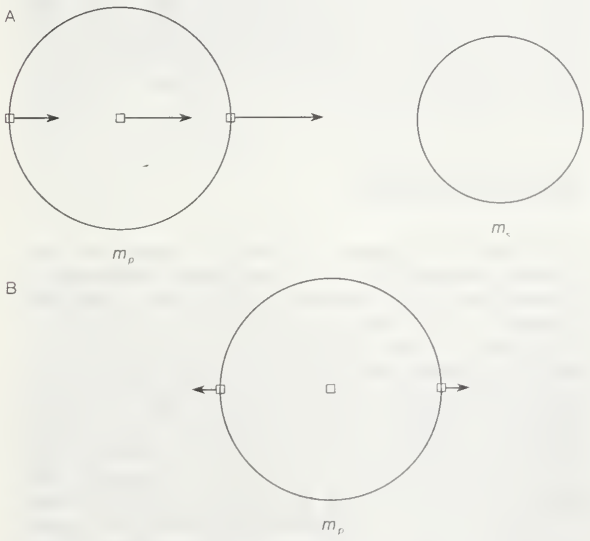

Figure 29: Variation of gravitational acceleration across a finite-sized body leading to differential acceleration relative to its centre (see text).

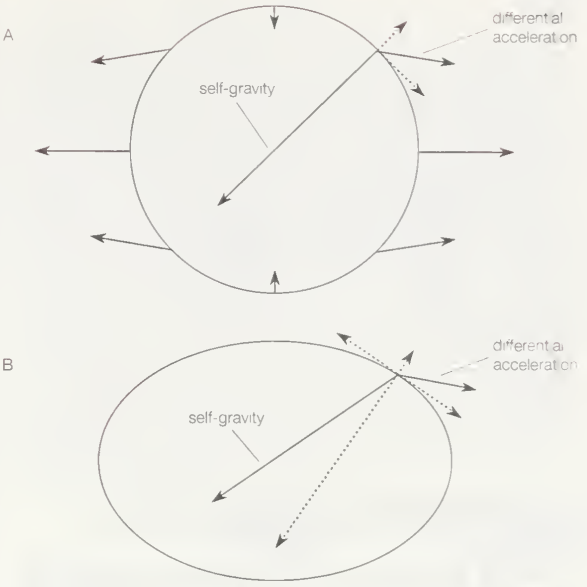

Figure 30: (A) Uncompensated tangential accelerations cause (B) tidal distortions in which all the differential accelerations are balanced by the change in the self-gravitational acceleration resulting from the distortion and by internal stresses (see text).

the differential acceleration due to the gravitational attraction of m_s, thus the elements do not fly off. If m_p were incompressible and perfectly rigid, the mass elements on the surface would weigh a little less than they would if m_s were not there but would not move relative to the centre of m_p. If m_p were fluid or otherwise not rigid, it would distort into an oval shape in the presence of m_s. The reason for this distortion is that the mass elements making up m_p that do not lie on the line joining the centres of m_p and m_s also experience a differential acceleration. Such differential accelerations are not perpendicular to the surface, however, and are therefore not compensated by the self-gravity that accelerates mass elements toward the centre of m_p. This is shown in Figure 30A, where one of the differential accelerations is resolved into two components (dotted arrows), one perpendicular and one tangential to the surface. The perpendicular component is compensated by the self-gravity; the tangential component is not. If m_p were entirely fluid, the uncompensated tangential components of the differential accelerations due to m_s would cause mass to flow toward the points on m_p that were either closest to m_s or farthest from m_s until m_p would resemble Figure 30B. In this shape the self-gravity is no longer perpendicular to the surface but has a component opposite the tangential component of the differential acceleration. Only in this distorted shape will all the differential accelerations be compensated and the entire body accelerated like the centre. If m_p is not fluid but is rigid like rock or iron, part of the compensating acceleration will be provided by internal stress forces, and the body will distort less. As no material is perfectly rigid, there is always some tidal bulge, and compressibility of the material will farther enhance this bulge. Note that the tidal distortion is independent of the orbital motion and would also occur if m_p and m_s were simply falling toward each other. (There is a similar tide raised on m_s by m_p that will be ignored for the present.)

High and low tides

If m_p rotates relative to m_s, an observer on the surface of m_p would successively rotate through the maxima and minima of the tidal distortion, which would tend to remain aligned with the direction to m_s. The observer would thereby experience two high and two low tides a day, as observed on Earth. Some of the energy of motion of any fluid parts of m_p and some of the energy stored as distortion of the solid parts as the tides wax and wane is converted into heat, and this dissipation of mechanical energy causes a delay in the response of the body to the tide-raising force. This means that high tide would occur at a given point on m_p as it rotates relative to m_s after m_s passes overhead. (On the Earth, the continents alter

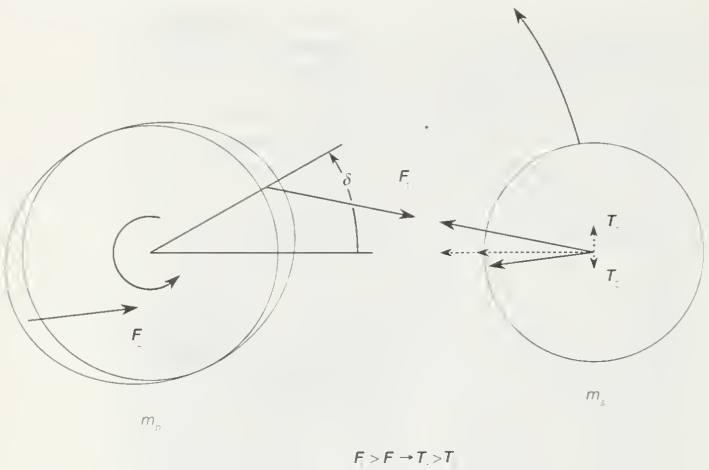

Figure 31: Unequal forces on two tidal bulges, leading to retardation of the spin of m_p and an acceleration of m_s in its orbit (see text).

the motion of the fluid ocean so much that ocean tides at continental coasts do not always lag the passage of the Moon overhead.) If m_p rotates in the same direction as m_s revolves in its orbit, the tidal bulge is carried ahead of m_s, as shown in Figure 31 by angle δ. Again, because the gravitational force between two masses varies as the inverse square of their separation, the tidal bulge closest to m_s experiences a greater attraction toward m_s (F_1 in Figure 31) than does the bulge farthest away (F_2). As these two forces are not aligned with the centre of m_p, there is a twisting effect, or torque, on m_p that retards its rate of rotation. This retardation will continue until the rotation is synchronous with the mean orbital motion of m_s. This has happened for the Moon, which keeps the same face toward the Earth.

From Newton's third law, there are equal and opposite forces acting on m_s corresponding to F_1 and F_2. In Figure 31 these forces are represented as T_1 and T_2, and each has been resolved into two components, one directed toward the centre of m_p and the other perpendicular to this direction. The inequality of these forces causes a net acceleration of m_s in its orbit, which thereby expands, as is observed for the Moon. Both the observed increase in the length of one day of 0.0016 second per century and the observed recession of the Moon of 3 to 4 centimetres per year are understood as consequences of the tides raised on the Earth.

In Figure 31, it has been assumed that the spin axis of m_p is perpendicular to the plane of the orbit of m_s. If the spin axis is inclined to this plane, the tidal bulge is carried out of the plane as well as ahead of m_s. This means that there is a twist, or torque, that changes the direction of the spin axis, so both the magnitude of spin and the direction of the spin axis experience a tidal evolution. The end point of tidal evolution for the spin state of one body of an isolated pair is rotation synchronous with the mean orbital motion with the spin axis perpendicular to the orbit plane. This simple picture is complicated somewhat if other perturbations cause the orbital plane to precess. This precession for the lunar orbit causes its spin axis to be inclined 6°41′ to the orbit plane as the end point of tidal evolution.

In addition to those of the Earth-Moon pair, numerous other consequences of tidal dissipation and the resulting evolution can be observed in the solar system and elsewhere in the Milky Way Galaxy. For example, all the major and close planetary satellites but one are observed to be rotating synchronously with their orbital motion. The exception is Saturn's satellite Hyperion. Tidal friction has indeed retarded Hyperion's initial spin rate to a value near that of synchronous rotation, but the combination of Hyperion's unusually asymmetric shape and its high orbital eccentricity leads to gravitational torques that make synchronous rotation unstable. As a result, the tides have brought Hyperion to a state where it tumbles chaotically with large changes in the direction and magnitude of its spin on time scales comparable to its orbital period of about 21 days.

Saturn-Hyperion tidal interactions

The assembly and maintenance of several orbital resonances among the satellites because of differential tidal expansion of the orbits have also been observed. The orbital resonances among Jupiter's satellites Io, Europa, and Ganymede, where the orbital periods are nearly in the ratio 1:2:4, maintain Io's orbital eccentricity at the value of 0.0041. This rather modest eccentricity causes sufficient variation in the magnitude and direction of Io's enormous tidal bulge to have melted a significant fraction of the satellite through dissipation of tidal energy in spite of Io's synchronous rotation. As a result, Io is the most volcanically active body in the solar system. The orbital eccentricity would normally be damped to zero by this large dissipation, but the orbital resonances with Europa and Ganymede prevent this from happening.

The distant planet Pluto and its satellite Charon are the only pair in the solar system that have almost certainly reached the ultimate end point where further tidal evolution has ceased altogether (the tiny tides raised by the Sun and other planets being neglected). In this state the orbit is circular, with both bodies rotating synchronously with the orbital motion and both spin axes perpendicular to the orbital plane.

The spin of the planet Mercury has been slowed by tides raised by the Sun to a final state where the spin angular velocity is exactly 1.5 times the orbital mean motion. This state is stable against further change because Mercury's high orbital eccentricity (0.206) allows restoring torques on the permanent (nontidal) axial asymmetry of the planet, which keeps the longest equatorial axis aligned with the direction to the Sun at perihelion. The tidal reduction of Mercury's average eccentricity (near 0.2) will cause insufficient change during the remaining lifetime of the Sun to disrupt this spin-orbit resonance. Finally, many close binary stars are observed to have circular orbits and synchronized spins—an example of tidal evolution elsewhere in the Milky Way Galaxy. (S.J.P.)

RELATIVISTIC MECHANICS

Relativistic mechanics is concerned with the motion of bodies whose relative velocities approach the speed of light c, or whose kinetic energies are comparable with the product of their masses m and the square of the velocity of light, or mc^2. Such bodies are said to be relativistic, and when their motion is studied it is necessary to take into account Einstein's special theory of relativity. As long as gravitational effects can be ignored, which will be true so long as gravitational potential energy differences are small compared with mc^2, the effects of Einstein's general theory of relativity may be safely ignored.

Special relativity

The bodies concerned may be sufficiently small that one may ignore their internal structure and size and regard them as point particles, in which case one speaks of relativistic point-particle mechanics; or one may need to take into account their internal structure, in which case one speaks of relativistic continuum mechanics. This article is concerned only with relativistic point-particle mechanics. It is also assumed that quantum mechanical effects are unimportant, otherwise relativistic quantum mechanics or relativistic quantum field theory—the latter theory being a quantum mechanical extension of relativistic continuum mechanics—would have to be considered. The condition that allows quantum effects to be safely ignored is that the sizes and separations of the bodies concerned are larger than their Compton wavelengths. (The Compton wavelength of a body of mass m is given by h/mc, where h is Planck's constant.) Despite these restrictions, there are nevertheless a number of situations in nature where relativistic mechanics is applicable. For example, it is es-

sential to take into account the effects of relativity when calculating the motion of elementary particles accelerated to higher energies in particle accelerators, such as those at CERN (European Organization for Nuclear Research) near Geneva or at Fermilab (Fermi National Accelerator Laboratory) near Chicago. Moreover, such particles are caused to collide, thus creating further particles; although this creation process can only be understood through quantum mechanics, once the particles are well separated, they are subject to the laws of special relativity.

Similar remarks apply to cosmic rays that reach the Earth from outer space. In some cases, these have energies as high as 10^{20} electron volts (eV). An electron of that energy has a velocity that differs from that of light by about 1 part in 10^{28}, as can be seen from the relativistic relation between energy and velocity, which will be given later. For a proton of the same energy, the velocity would differ from that of light by about 1 part in 10^{22}. At a more mundane level, relativistic mechanics must be used to calculate the energies of electrons or positrons emitted by the decay of radioactive nuclei. Astrophysicists need to use relativistic mechanics when dealing with the energy sources of stars, the energy released in supernova explosions, and the motion of electrons moving in the atmospheres of pulsars or when considering the hot big bang. At temperatures in the very early universe above 10^{10} kelvins (K), at which typical thermal energies kT (where k is Boltzmann's constant and T is temperature) are comparable with the rest mass energy of the electron, the primordial plasma must have been relativistic. Relativistic mechanics also must be considered when dealing with satellite navigational systems used, for example, by the military, such as the Global Positioning System (GPS). In this case, however, it is the purely kinematic effect on the rate of clocks on board the satellites (*i.e.*, time dilation) that is important rather than the dynamic effects of relativity on the motion of the satellites themselves.

DEVELOPMENT OF THE SPECIAL THEORY OF RELATIVITY

Inertial frames of reference

Since the time of Galileo it has been realized that there exists a class of so-called inertial frames of reference—*i.e.*, in a state of uniform motion with respect to one another such that one cannot, by purely mechanical means, distinguish one from the other. It follows that the laws of mechanics must take the same form in every inertial frame of reference. To the accuracy of present-day technology, the class of inertial frames may be regarded as those that are neither accelerating nor rotating with respect to the distant galaxies. To specify the motion of a body relative to a frame of reference, one gives its position $\boldsymbol{x}$ as a function of a time coordinate t ($\boldsymbol{x}$ is called the position vector and has the components x, y, and z).

Newton's first law of motion (which remains true in special relativity) states that a body acted upon by no external forces will continue to move in a state of uniform motion relative to an inertial frame. It follows from this that the transformation between the coordinates $(t, \boldsymbol{x})$ and $(t', \boldsymbol{x}')$ of two inertial frames with relative velocity $\boldsymbol{u}$ must be related by a linear transformation. Before Einstein's special theory of relativity was published in 1905, it was usually assumed that the time coordinates measured in all inertial frames were identical and equal to an "absolute time." Thus,

$$t = t'. \tag{97}$$

The position coordinates $\boldsymbol{x}$ and $\boldsymbol{x}'$ were then assumed to be related by

$$\boldsymbol{x}' = \boldsymbol{x} - \boldsymbol{u}t. \tag{98}$$

The two formulas (97) and (98) are called a Galilean transformation. The laws of nonrelativistic mechanics take the same form in all frames related by Galilean transformations. This is the restricted, or Galilean, principle of relativity.

The position of a light-wave front speeding from the origin at time zero should satisfy

$$\boldsymbol{x}^2 - c^2t^2 = 0 \tag{99}$$

in the frame $(t, \boldsymbol{x})$ and

$$(\boldsymbol{x}')^2 - c^2(t')^2 = 0 \tag{100}$$

in the frame $(t', \boldsymbol{x}')$. Formula (100) does not transform into formula (99) using the Galilean transformations (97) and (98), however. Put another way, if one uses Galilean transformations one finds that the velocity of light depends on one's inertial frame, which is contrary to the Michelson-Morley experiment (see RELATIVITY). Einstein realized that either it is possible to determine a unique absolute frame of rest relative to which the motion of a light wave is given by equation (99) and its velocity is c only in that frame or the assumption that all inertial observers measure the same absolute time t—*i.e.*, formula (97)—must be wrong. Since he believed in (and experiment confirmed) the (extended) principle of relativity, which meant that one cannot, by any means, including the use of light waves, distinguish between two inertial frames in uniform relative motion, Einstein chose to give up the Galilean transformations (97) and (98) and replaced them with the Lorentz transformations:

Lorentz transformations

$$t' = \frac{(t - \boldsymbol{u}\cdot\boldsymbol{x}/c^2)}{\sqrt{1 - \boldsymbol{u}^2/c^2}}, \tag{101}$$

$$\boldsymbol{x}'_{\parallel} = \frac{(\boldsymbol{x}_{\parallel} - \boldsymbol{u}t)}{\sqrt{1 - \boldsymbol{u}^2/c^2}}. \tag{102a}$$

$$\boldsymbol{x}'_{\perp} = \boldsymbol{x}_{\perp}, \tag{102b}$$

where $\boldsymbol{x}_{\parallel}$ and $\boldsymbol{x}_{\perp}$ are the projections of $\boldsymbol{x}$ parallel and perpendicular to the velocity $\boldsymbol{u}$, respectively, and similarly for $\boldsymbol{x}'$.

The reader may check that substitution of the Lorentz transformation formulas (101) and (102) into the left-hand side of equation (100) results in the left-hand side of equation (99). For simplicity, it has been assumed here and throughout this discussion, that the spatial axes are not rotated with respect to one another. Even in this case one sometimes considers Lorentz transformations that are more general than those of equations (101) and (102). These more general transformations may reverse the sense of time; *i.e.*, t and t' may have opposite signs or may reverse spatial orientation or parity. To distinguish this more general class of transformations from those of equations (101) and (102), one sometimes refers to (101) and (102) as proper Lorentz transformations.

The laws of light propagation are the same in all frames related by Lorentz transformations, and the velocity of light is the same in all such frames. The same is true of Maxwell's laws of electromagnetism. However, the usual laws of mechanics are not the same in all frames related by Lorentz transformations and thus must be altered to agree with the principle of relativity.

The unique absolute frame of rest with respect to which light waves had velocity c according to the prerelativistic viewpoint was often regarded, before Einstein, as being at rest relative to a hypothesized all-pervading ether. The vibrations of this ether were held to explain the phenomenon of electromagnetic radiation. The failure of experimenters to detect motion relative to this ether, together with the widespread acceptance of Einstein's special theory of relativity, led to the abandonment of the theory of the ether. It is ironic therefore to note that the discovery in 1964 by the American astrophysicists Arno Penzias and Robert Wilson of a universal cosmic microwave 3 K radiation background shows that the universe does indeed possess a privileged inertial frame. Nevertheless, this does not contradict special relativity because one cannot measure the Earth's velocity relative to it by experiments in a closed laboratory. One must actually detect the microwaves themselves.

If the relative velocity $\boldsymbol{u}$ between inertial frames is small in magnitude compared with the velocity of light, then Galilean transformations and Lorentz transformations agree, as do the usual laws of nonrelativistic mechanics and the more accurate laws of relativistic mechanics. The requirement that the laws of physics take the same form in all inertial reference frames related by Lorentz transfor-

mations is called for the sake of brevity the requirement of relativistic invariance. It has become a powerful guide in the formation of new physical theories.

RELATIVISTIC SPACE-TIME

The modification of the usual laws of mechanics may be understood purely in terms of the Lorentz transformation formulas (101) and (102). It was pointed out, however, by the German mathematician Hermann Minkowski in 1908, that the Lorentz transformations have a simple geometric interpretation that is both beautiful and useful. The motion of a particle may be regarded as forming a curve made up of points, called events, in a four-dimensional space whose four coordinates comprise the three spatial coordinates $\boldsymbol{x} \equiv (x, y, z)$ and the time t.

Minkowski space-time

The four-dimensional space is called Minkowski space-time and the curve a world line. It is frequently useful to represent physical processes by space-time diagrams in which time runs vertically and the spatial coordinates run horizontally. Of course, since space-time is four-dimensional, at least one of the spatial dimensions in the diagram must be suppressed.

Newton's first law can be interpreted in four-dimensional space as the statement that the world lines of particles suffering no external forces are straight lines in space-time. Linear transformations take straight lines to straight lines, and Lorentz transformations have the additional property that they leave invariant the invariant interval τ through two events $(t_1, \boldsymbol{x}_1)$ and $(t_2, \boldsymbol{x}_2)$ given by

$$\tau^2 = (t_1 - t_2)^2 - \frac{(\boldsymbol{x}_1 - \boldsymbol{x}_2)^2}{c^2} . \qquad (103)$$

If the right-hand side of equation (103) is zero, the two events may be joined by a light ray and are said to be on each other's light cones because the light cone of any event $(t, \boldsymbol{x})$ in space-time is the set of points reachable from it by light rays (see Figure 32). Thus the set of all events $(t_2, \boldsymbol{x}_2)$ satisfying equation (103) with zero on the right-hand side is the light cone of the event $(t_1, \boldsymbol{x}_1)$. Because Lorentz transformations leave invariant the space-time interval (103), all inertial observers agree on what the light cones are. In space-time diagrams it is customary to adopt a scaling of the time coordinate such that the light cones have a half angle of 45°.

If the right-hand side of equation (103) is strictly positive, in which case one says that the two events are timelike separated, or have a timelike interval, then one can find an inertial frame with respect to which the two events have the same spatial position. The straight world line joining the two events corresponds to the time axis of this inertial frame of reference. The quantity τ is equal to the difference in time between the two events in this inertial frame and is called the proper time between the two events. The proper time would be measured by any clock moving along the straight world line between the two events.

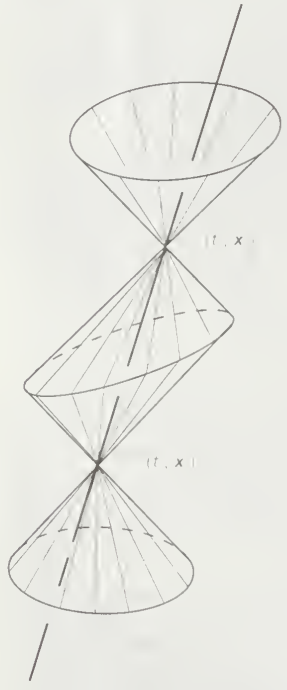

Figure 32: The world line of a particle traveling with speed less than that of light.

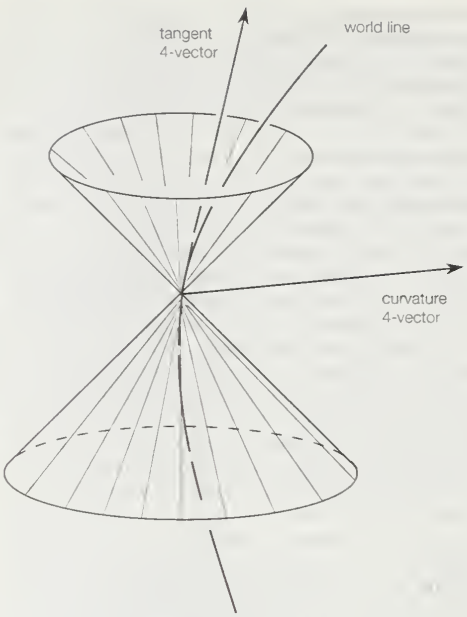

Figure 33: The world line of an accelerating body moving slower than the speed of light; the tangent vector corresponds to the body's 4-velocity and the curvature vector to its 4-acceleration.

An accelerating body will have a curved world line that may be specified by giving its coordinates t and $\boldsymbol{x}$ as a function of the proper time τ along the world line. The laws of either may be phrased in terms of the more familiar velocity $\boldsymbol{v} = d\boldsymbol{x}/dt$ and acceleration $\boldsymbol{a} = d^2\boldsymbol{x}/dt^2$ or in terms of the 4-velocity $(dt/d\tau, d\boldsymbol{x}/d\tau)$ and 4-acceleration $(d^2t/d\tau^2, d\boldsymbol{x}/d\tau^2)$. Just as an ordinary vector like $\boldsymbol{v}$ has three components, v_x, v_y, and v_z, a 4-vector has four components. Geometrically the 4-velocity and 4-acceleration correspond, respectively, to the tangent vector and the curvature vector of the world line (see Figure 33). If the particle moves slower than light, the tangent, or velocity, vector at each event on the world line points inside the light cone of that event, and the acceleration, or curvature, vector points outside the light cone. If the particle moves with the speed of light, then the tangent vector lies on the light cone at each event on the world line. The proper time τ along a world line moving with a speed less than light is not an independent quantity from t and $\boldsymbol{x}$: it satisfies

4-vectors

$$\left(\frac{dt}{d\tau}\right)^2 - \frac{1}{c^2}\left(\frac{d\boldsymbol{x}}{d\tau}\right)^2 = 1. \qquad (104)$$

For a particle moving with exactly the speed of light, one cannot define a proper time τ. One can, however, define a so-called affine parameter that satisfies equation (104) with zero on the right-hand side. For the time being this discussion will be restricted to particles moving with speeds less than light.

Equation (104) does not fix the sign of τ relative to that of t. It is usual to resolve this ambiguity by demanding that the proper time τ increase as the time t increases. This requirement is invariant under Lorentz transformations of the form of equations (101) and (102). The tangent vector then points inside the future light cone and is said to be future-directed and timelike (see Figure 34). One may if one wishes attach an arrow to the world line to indicate this fact. One says that the particle moves forward in time. It was pointed out by the Swiss physicist Ernest C.G. Stückelberg de Breidenbach and by the American physicist Richard Feynman that a meaning can be attached to world lines moving backward in time—*i.e.*, for those for

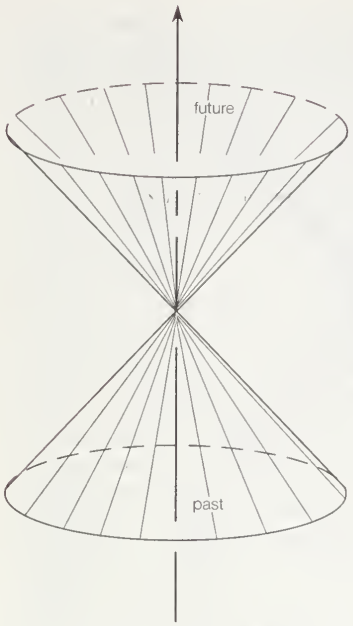

Figure 34: The world line of a particle moving forward in time (see text).

which ordinary time t decreases as proper time τ increases. Since, as shall be shown later, the energy E of a particle is $mc^2 dt/d\tau$, such world lines correspond to the motion of particles with negative energy. It is possible to interpret these world lines in terms of antiparticles, as will be seen when particles moving in a background electromagnetic field are considered.

The fundamental laws of motion for a body of mass m in relativistic mechanics are

$$m\frac{d^2t}{d\tau^2} = f^0 \tag{105}$$

and

$$m\frac{d^2\boldsymbol{x}}{d\tau^2} = \boldsymbol{f}, \tag{106}$$

where m is the constant so-called rest mass of the body and the quantities $(f^0, \boldsymbol{f})$ are the components of the force 4-vector. Equations (105) and (106), which relate the curvature of the world line to the applied forces, are the same in all inertial frames related by Lorentz transformations. The quantities $(mdt/d\tau, m\boldsymbol{dx}/d\tau)$ make up the 4-momentum of the particle. According to Minkowski's reformulation of special relativity, a Lorentz transformation may be thought of as a generalized rotation of points of Minkowski space-time into themselves. It induces an identical rotation on the 4-acceleration and force 4-vectors. To say that both of these 4-vectors experience the same generalized rotation or Lorentz transformation is simply to say that the fundamental laws of motion (105) and (106) are the same in all inertial frames related by Lorentz transformations. Minkowski's geometric ideas provided a powerful tool for checking the mathematical consistency of special relativity and for calculating its experimental consequences. They also have a natural generalization in the general theory of relativity, which incorporates the effects of gravity.

Rotation in space-time

RELATIVISTIC MOMENTUM, MASS, AND ENERGY

The law of motion (106) may also be expressed as:

$$\frac{d}{dt}\left(\frac{m\boldsymbol{v}}{\sqrt{1-\boldsymbol{v}^2/c^2}}\right) = \boldsymbol{F}, \tag{107}$$

where $\boldsymbol{F} = \boldsymbol{f}\sqrt{1-\boldsymbol{v}^2/c^2}$. Equation (107) is of the same form as Newton's second law of motion, which states that the rate of change of momentum equals the applied force. $\boldsymbol{F}$ is the Newtonian force, but the Newtonian relation between momentum $\boldsymbol{p}$ and velocity $\boldsymbol{v}$ in which $\boldsymbol{p} = m\boldsymbol{v}$ is modified to become

$$\boldsymbol{p} = \frac{m\boldsymbol{v}}{\sqrt{1-\boldsymbol{v}^2/c^2}}. \tag{108}$$

Consider a relativistic particle with positive energy and electric charge q moving in an electric field $\boldsymbol{E}$ and magnetic field $\boldsymbol{B}$; it will experience an electromagnetic, or Lorentz, force given by $\boldsymbol{F} = q\boldsymbol{E} + q\boldsymbol{v}\times\boldsymbol{B}$. If $t(\tau)$ and $\boldsymbol{x}(\tau)$ are the time and space coordinates of the particle, it follows from equations (105) and (106), with $f^0 = (q\boldsymbol{E}\cdot\boldsymbol{v})dt/d\tau$ and $\boldsymbol{f} = q(\boldsymbol{E}+\boldsymbol{v}\times\boldsymbol{B})dt/d\tau$, that $-t(-\tau)$ and $-\boldsymbol{x}(-\tau)$ are the coordinates of a particle with positive energy and the opposite electric charge $-q$ moving in the same electric and magnetic field. A particle of the opposite charge but with the same rest mass as the original particle is called the original particle's antiparticle. It is in this sense that Feynman and Stückelberg spoke of antiparticles as particles moving backward in time. This idea is a consequence of special relativity alone. It really comes into its own, however, when one considers relativistic quantum mechanics.

Antiparticles

Just as in nonrelativistic mechanics, the rate of work done when the point of application of a force $\boldsymbol{F}$ is moved with velocity $\boldsymbol{v}$ equals $\boldsymbol{F}\cdot\boldsymbol{v}$ when measured with respect to the time coordinate t. This work goes into increasing the energy E of the particle. Taking the dot product of equation (107) with $\boldsymbol{v}$ gives

$$\frac{dE}{dt} = \boldsymbol{F}\cdot\boldsymbol{v}, \tag{109a}$$

where

$$E = \frac{mc^2}{\sqrt{1-\boldsymbol{v}^2/c^2}} = mc^2\frac{dt}{d\tau}. \tag{109b}$$

The reader should note that the 4-momentum is just $(E/c^2, \boldsymbol{p})$. It was once fairly common to encounter the use of a "velocity-dependent mass" equal to E/c^2. However, experience has shown that its introduction serves no useful purpose and may lead to confusion, and it is not used in this article. The invariant quantity is the rest mass m. For that reason it has not been thought necessary to add a subscript or superscript to m to emphasize that it is the rest mass rather than a velocity-dependent quantity. When subscripts are attached to a mass, they indicate the particular particle of which it is the rest mass.

If the applied force $\boldsymbol{F}$ is perpendicular to the velocity $\boldsymbol{v}$, it follows from equation (109) that the energy E, or, equivalently, the velocity squared $\boldsymbol{v}^2$, will be constant, just as in Newtonian mechanics. This will be true, for example, for a particle moving in a purely magnetic field with no electric field present. It then follows from equation (107) that the shape of the orbits of the particle are the same according to the classical and the relativistic equations. However, the rate at which the orbits are traversed differs according to the two theories. If w is the speed according to the nonrelativistic theory and v that according to special relativity, then $w = v\sqrt{1-v^2/c^2}$.

For velocities that are small compared with that of light,

$$E \approx mc^2 + \frac{1}{2}m\boldsymbol{v}^2. \tag{110}$$

The first term, mc^2, which remains even when the particle is at rest, is called the rest mass energy. For a single particle, its inclusion in the expression for energy might seem to be a matter of convention: it appears as an arbitrary constant of integration. However, for systems of particles that undergo collisions, its inclusion is essential.

Both theory and experiment agree that, in a process in which particles of rest masses $m_1, m_2, \ldots m_n$ collide or decay or transmute one into another, both the total energy $E_1 + E_2 + \ldots + E_n$ and the total momentum $\boldsymbol{p}_1 + \boldsymbol{p}_2 + \ldots + \boldsymbol{p}_n$ are the same before and after the process, even though the number of particles may not be the same before and after. This corresponds to conservation of the total 4-momentum $(E_1 + E_2 + \ldots + E_n)/c^2$, $\boldsymbol{p}_1 + \boldsymbol{p}_2 + \ldots + \boldsymbol{p}_n)$.

Law of energy-momentum conservation

The relativistic law of energy-momentum conservation thus combines and generalizes in one relativistically invariant expression the separate conservation laws of prerelativistic physics: the conservation of mass, the conservation

of momentum, and the conservation of energy. In fact, the law of conservation of mass becomes incorporated in the law of conservation of energy and is modified if the amount of energy exchanged is comparable with the rest mass energy of any of the particles.

For example, if a particle of mass M at rest decays into two particles the sum of whose rest masses $m_1 + m_2$ is smaller than M (see Figure 35), then the two momenta $\boldsymbol{p}_1$ and $\boldsymbol{p}_2$ must be equal in magnitude and opposite in direction. The quantity $T = E - mc^2$ is the kinetic energy of the particle. In such a decay the initial kinetic energy is zero. Since the conservation of energy implies that in the process $Mc^2 = T_1 + T_2 + m_1c^2 + m_2c^2$, one speaks of the conversion of an amount $(M - m_1 - m_2)c^2$ of rest mass energy to kinetic energy. It is precisely this process that provides the large amount of energy available during nuclear fission, for example, in the spontaneous fission of the uranium-235 isotope. The opposite process occurs in nuclear fusion when two particles fuse to form a particle of smaller total rest mass. The difference $(m_1 + m_2 - M)$ multiplied by c^2 is called the binding energy. If the two initial particles are both at rest, a fourth particle is required to satisfy the conservation of energy and momentum. The rest mass of this fourth particle will not change, but it will acquire kinetic energy equal to the binding energy minus the kinetic energy of the fused particles. Perhaps the most important examples are the conversion of hydrogen to helium in the centre of stars, such as the Sun, and during thermonuclear reactions used in atomic bombs.

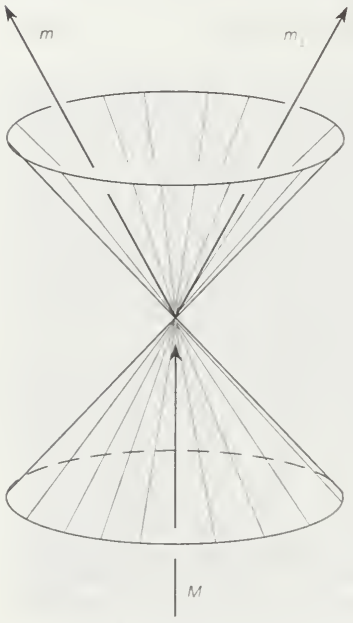

Figure 35: The decay of a particle of mass M into two particles the sum of whose rest masses is less than M (see text).

This article has so far dealt only with particles with non-vanishing rest mass whose velocities must always be less than that of light. One may always find an inertial reference frame with respect to which they are at rest and their energy in that frame equals mc^2. However, special relativity allows a generalization of classical ideas to include particles with vanishing rest masses that can move only with the velocity of light. Particles in nature that correspond to this possibility and that could not, therefore, be incorporated into the classical scheme are the photon, which is associated with the transmission of electromagnetic radiation, three species of neutrinos associated with the weak interaction responsible for radioactive decay, and—more speculatively—the graviton, which plays the same role with respect to gravitational waves as does the photon with respect to electromagnetic waves. Strictly speaking, it is not yet known whether the rest masses of the three neutrino species vanish, but in many processes their energies exceed their possible rest masses by so much that they may be regarded as effectively massless. The velocity v of any particle in relativistic mechanics is given by $v = pc^2/E$, and the relation between energy E and momentum is $E^2 = m^2c^4 + p^2c^2$. Thus for massless particles $E = |\boldsymbol{p}|c$ and the 4-momentum is given by $(|\boldsymbol{p}|/c, \boldsymbol{p})$. It follows from the relativistic laws of energy and momentum conservation that, if a massless particle were to decay, it could do so only if the particles produced were all strictly massless and their momenta $\boldsymbol{p}_1, \boldsymbol{p}_2, \ldots \boldsymbol{p}_n$ were all strictly aligned with the momentum $\boldsymbol{p}$ of the original massless particle. Since this is a situation of vanishing likelihood, it follows that strictly massless particles are absolutely stable.

Stability of massless particles

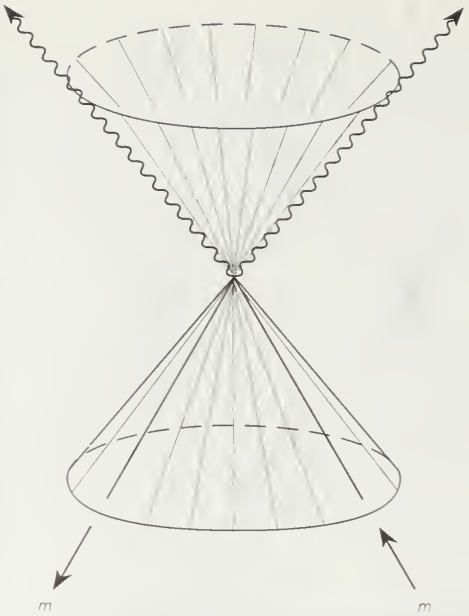

Figure 36: The world lines of an electron (moving forward in time) and a positron (moving backward in time) that annihilate into two photons (see text).

It also follows that one or more massive particles cannot decay into a single massless particle, conserving both energy and momentum. They can, however, decay into two or more massless particles, and indeed this is observed in the decay of the neutral pion into photons and in the annihilation of an electron and a positron pair into photons. In the latter case, the world lines of the annihilating particles meet at the space-time event where they annihilate. Using the interpretation of Feynman and Stückelberg, one may view these two world lines as a single continuous world line with two portions, one moving forward in time and one moving backward in time (see Figure 36). This interpretation plays an important role in the quantum theory of such processes. (G.W.G.)

MECHANICS OF SOLIDS

The application of the principles of mechanics to bulk matter is conventionally divided into the mechanics of fluids and the mechanics of solids. The entire subject is often called continuum mechanics, particularly when matter is assumed to be continuously divisible and no reference is made to its discrete structure at microscopic scales well below those of the application or phenomenon of interest.

Solid mechanics is concerned with the stressing, deformation, and failure of solid materials and structures. What, then, is a solid? Any material, fluid or solid, can support normal forces. These are forces directed perpendicular, or normal, to a material plane across which they act. The force per unit of area of that plane is called the normal stress. Water at the base of a pond, air in an automobile

tire, the stones of a Roman arch, rocks at the base of a mountain, the skin of a pressurized airplane cabin, a stretched rubber band, and the bones of a runner all support force in that way (some only when the force is compressive). A material is called solid rather than fluid if it can also support a substantial shearing force over the time scale of some natural process or technological application of interest. Shearing forces are directed parallel, rather than perpendicular, to the material surface on which they act; the force per unit of area is called shear stress. For example, consider a vertical metal rod that is fixed to a support at its upper end and has a weight attached at its lower end. If one considers a horizontal surface through the material of the rod, it will be evident that the rod supports normal stress. But it also supports shear stress, and this becomes evident when one considers the forces carried across a plane that is neither horizontal nor vertical through the rod. Thus, while water and air provide no long-term support of shear stress, granite, steel, and rubber normally do so and are therefore called solids. Materials with tightly bound atoms or molecules, such as the crystals formed below melting temperature by most substances or simple compounds and the amorphous structures formed in glass and many polymer substances at sufficiently low temperature, are usually considered solids.

Definition of a solid

The distinction between solids and fluids is not precise and in many cases will depend on the time scale. Consider the hot rocks of the Earth's mantle. When a large earthquake occurs, an associated deformation disturbance called a seismic wave propagates through the adjacent rock, and the entire Earth is set into vibrations which, following a sufficiently large earthquake, may remain detectable with precise instruments for several weeks. The rocks of the mantle are then described as solid—as they would also be on the time scale of, say, tens to thousands of years, over which stresses rebuild enough in the source region to cause one or a few repetitions of the earthquake. But on a significantly longer time scale, say, on the order of a million years, the hot rocks of the mantle are unable to support shearing stresses and flow as a fluid. The substance called Silly Putty (trademark), a polymerized silicone gel familiar to many children, is another example. If a ball of it is left to sit on a table at room temperature, it flows and flattens on a time scale of a few minutes to an hour. But if picked up and tossed as a ball against a wall, so that large forces act only over the short time of the impact, the Silly Putty bounces back and retains its shape like a highly elastic solid.

Types of solid deformation

Several types of solids can be distinguished according to their mechanical behaviour. In the simple but common case when a solid material is loaded at a sufficiently low temperature or short time scale, and with sufficiently limited stress magnitude, its deformation is fully recovered upon unloading. The material is then said to be elastic. But substances can also deform permanently, so that not all the deformation is recovered. For example, if one bends a metal coat hanger substantially and then releases the loading, it springs back only partially toward its initial shape; it does not fully recover but remains bent. The metal of the coat hanger has been permanently deformed, and in this case, for which the permanent deformation is not so much a consequence of longtime loading at sufficiently high temperature but more a consequence of subjecting the material to large stresses (above the yield stress), the permanent deformation is described as a plastic deformation and the material is called elastic-plastic. Permanent deformation of a sort that depends mainly on time of exposure to a stress—and that tends to increase significantly with time of exposure—is called viscous, or creep, deformation, and materials that exhibit those characteristics, as well as tendencies for elastic response, are called viscoelastic solids (or sometimes viscoplastic solids, when the permanent strain is emphasized rather than the tendency for partial recovery of strain upon unloading).

Solid mechanics has many applications. All those who seek to understand natural phenomena involving the stressing, deformation, flow, and fracture of solids, as well as all those who would have knowledge of such phenomena to improve living conditions and accomplish human objectives, have use for solid mechanics. The latter activities are, of course, the domain of engineering, and many important modern subfields of solid mechanics have been actively developed by engineering scientists concerned, for example, with mechanical, structural, materials, civil, or aerospace engineering. Natural phenomena involving solid mechanics are studied in geology, seismology, and tectonophysics, in materials science and the physics of condensed matter, and in some branches of biology and physiology. Furthermore, because solid mechanics poses challenging mathematical and computational problems, it (as well as fluid mechanics) has long been an important topic for applied mathematicians concerned, for example, with partial differential equations and with numerical techniques for digital computer formulations of physical problems.

Issues addressed by solid mechanics

Here is a sampling of some of the issues addressed using solid mechanics concepts: How do flows develop in the Earth's mantle and cause continents to move and ocean floors to subduct (*i.e.*, be thrust) slowly beneath them? How do mountains form? What processes take place along a fault during an earthquake, and how do the resulting disturbances propagate through the Earth as seismic waves, shaking, and perhaps collapsing, buildings and bridges? How do landslides occur? How does a structure on a clay soil settle with time, and what is the maximum bearing pressure that the footing of a building can exert on a soil or rock foundation without rupturing it? What materials should be chosen, and how should their proportion, shape, and loading be controlled, to make safe, reliable, durable, and economical structures—whether airframes, bridges, ships, buildings, chairs, artificial heart valves, or computer chips—and to make machinery such as jet engines, pumps, and bicycles? How do vehicles (cars, planes, ships) respond by vibration to the irregularity of surfaces or mediums along which they move, and how are vibrations controlled for comfort, noise reduction, and safety against fatigue failure? How rapidly does a crack grow in a cyclically loaded structure, whether a bridge, engine, or airplane wing or fuselage, and when will it propagate catastrophically? How can the deformability of structures during impact be controlled so as to design crashworthiness into vehicles? How are the materials and products of a technological civilization formed—*e.g.*, by extruding metals or polymers through dies, rolling material into sheets, punching out complex shapes, and so on? By what microscopic processes do plastic and creep strains occur in polycrystals? How can different materials, such as fibre-reinforced composites, be fashioned together to achieve combinations of stiffness and strength needed in specific applications? What is the combination of material properties and overall response needed in downhill skis or in a tennis racket? How does the human skull respond to impact in an accident? How do heart muscles control the pumping of blood in the human body, and what goes wrong when an aneurysm develops?

History

Solid mechanics developed in the outpouring of mathematical and physical studies following the great achievement of Newton in stating the laws of motion, although it has earlier roots. The need to understand and control the fracture of solids seems to have been a first motivation. Leonardo da Vinci sketched in his notebooks a possible test of the tensile strength of a wire. Galileo, who died in the year of Newton's birth (1642), had investigated the breaking loads of rods under tension and concluded that the load was independent of length and proportional to the cross section area, this being a first step toward a concept of stress. He also investigated the breaking loads on beams that were suspended horizontally from a wall into which they were built.

Concepts of stress, strain, and elasticity. The English scientist Robert Hooke discovered in 1660, but published only in 1678, that for many materials the displacement under a load was proportional to force, thus establishing the notion of (linear) elasticity but not yet in a way that was expressible in terms of stress and strain. Edme Mariotte in France published similar discoveries in 1680 and,

in addition, reached an understanding of how beams like those studied by Galileo resist transverse loadings—or, more precisely, resist the torques caused by those transverse loadings—by developing extensional and compressional deformations, respectively, in material fibres along their upper and lower portions. It was for the Swiss mathematician and mechanician Jakob Bernoulli to observe, in the final paper of his life, in 1705, that the proper way of describing deformation was to give force per unit area, or stress, as a function of the elongation per unit length, or strain, of a material fibre under tension. The Swiss mathematician and mechanician Leonhard Euler, who was taught mathematics by Jakob's brother Johann Bernoulli, proposed, among many contributions, a linear relation between stress σ and strain ε, in 1727, of the form $\sigma = E\varepsilon$, where the coefficient E is now generally called Young's modulus after the British naturalist Thomas Young, who developed a related idea in 1807.

Relation between stress and strain

The notion that there is an internal tension acting across surfaces in a deformed solid was expressed by the German mathematician and physicist Gottfried Wilhelm Leibniz in 1684 and Jakob Bernoulli in 1691. Also, Jakob Bernoulli and Euler introduced the idea that at a given section along the length of a beam there were internal tensions amounting to a net force and a net torque (see below). Euler introduced the idea of compressive normal stress as the pressure in a fluid in 1752. The French engineer and physicist Charles-Augustin Coulomb was apparently the first to relate the theory of a beam as a bent elastic line to stress and strain in an actual beam, in a way never quite achieved by Bernoulli and, although possibly recognized, never published by Euler. He developed the famous expression $\sigma = My/I$ for the stress due to the pure bending of a homogenous linear elastic beam; here M is the torque, or bending moment, y is the distance of a point from an axis that passes through the section centroid, parallel to the torque axis, and I is the integral of y^2 over the section area. The French mathematician Antoine Parent introduced the concept of shear stress in 1713, but Coulomb was the one who extensively developed the idea, first in connection with beams and with the stressing and failure of soil in 1773 and then in studies of frictional slip in 1779.

It was the great French mathematician Augustin-Louis Cauchy, originally educated as an engineer, who in 1822 formalized the concept of stress in the context of a generalized three-dimensional theory, showed its properties as consisting of a 3×3 symmetric array of numbers that transform as a tensor, derived the equations of motion for a continuum in terms of the components of stress, and developed the theory of linear elastic response for isotropic solids. As part of his work in this area, Cauchy also introduced the equations that express the six components of strain (three extensional and three shear) in terms of derivatives of displacements for the case in which all those derivatives are much smaller than unity; similar expressions had been given earlier by Euler in expressing rates of straining in terms of the derivatives of the velocity field in a fluid.

Contributions of Cauchy

Beams, columns, plates, and shells. The 1700s and early 1800s were a productive period during which the mechanics of simple elastic structural elements were developed—well before the beginnings in the 1820s of the general three-dimensional theory. The development of beam theory by Euler, who generally modeled beams as elastic lines that resist bending, as well as by several members of the Bernoulli family and by Coulomb, remains among the most immediately useful aspects of solid mechanics, in part for its simplicity and in part because of the pervasiveness of beams and columns in structural technology. Jakob Bernoulli proposed in his final paper of 1705 that the curvature of a beam was proportional to its bending moment. Euler in 1744 and Johann's son, Daniel Bernoulli, in 1751 used the theory to address the transverse vibrations of beams, and in 1757 Euler gave his famous analysis of the buckling of an initially straight beam subjected to a compressive loading; such a beam is commonly called a column. Following a suggestion of Daniel Bernoulli in 1742, Euler in 1744 introduced the concept of strain energy per unit length for a beam and showed that it is proportional to the square of the beam's curvature. Euler regarded the total strain energy as the quantity analogous to the potential energy of a discrete mechanical system. By adopting procedures that were becoming familiar in analytical mechanics and following from the principle of virtual work as introduced in 1717 by Johann Bernoulli for such discrete systems as pin-connected rigid bodies, Euler rendered the energy stationary and in this way developed the calculus of variations as an approach to the equations of equilibrium and motion of elastic structures.

That same variational approach played a major role in the development by French mathematicians in the early 1800s of a theory of small transverse displacements and vibrations of elastic plates. This theory was developed in preliminary form by Sophie Germain and was also worked on by Siméon-Denis Poisson in the early 1810s; they considered a flat plate as an elastic plane that resists curvature. Claude-Louis-Marie Navier gave a definitive development of the correct energy expression and governing differential equation a few years later. An uncertainty of some duration arose in the theory from the fact that the final partial differential equation for the transverse displacement is such that it is impossible to prescribe, simultaneously, along an unsupported edge of the plate, both the twisting moment per unit length of middle surface and the transverse shear force per unit length. This was finally resolved in 1850 by the Prussian physicist Gustav Robert Kirchhoff, who applied virtual work and variational calculus procedures in the framework of simplifying kinematic assumptions that fibres initially perpendicular to the plate's middle surface remain so after deformation of that surface.

The first steps in the theory of thin shells were taken by Euler in the 1770s; he addressed the deformation of an initially curved beam as an elastic line and provided a simplified analysis of the vibration of an elastic bell as an array of annular beams. Johann's grandson, Jakob Bernoulli "the Younger," further developed this model in the last year of his life as a two-dimensional network of elastic lines, but he could not develop an acceptable treatment. Shell theory did not attract attention again until a century after Euler's work. The first consideration of shells from a three-dimensional elastic viewpoint was advanced by Hermann Aron in 1873. Acceptable thin-shell theories for general situations, appropriate for cases of small deformation, were then developed by the British mathematician, mechanician, and geophysicist Augustus Edward Hough Love in 1888 and by the British mathematician and physicist Horace Lamb in 1890 (there is no uniquely correct theory, as the Dutch applied mechanician and engineer W.T. Koiter and the Soviet mechanician V.V. Novozhilov clarified in the 1950s; the difference between predictions of acceptable theories is small when the ratio of shell thickness to a typical length scale is small). Shell theory remained of immense interest well beyond the mid-1900s, in part because so many problems lay beyond the linear theory (rather small transverse displacements often dramatically alter the way that a shell supports load by a combination of bending and membrane action) and in part because of the interest in such lightweight structural forms for aeronautical technology.

The general theory of elasticity. Linear elasticity as a general three-dimensional theory began to be developed in the early 1820s based on Cauchy's work. Simultaneously, Navier had developed an elasticity theory based on a simple corpuscular, or particle, model of matter in which particles interacted with their neighbours by a central force attraction between particle pairs. As was gradually realized, following work by Navier, Cauchy, and Poisson in the 1820s and '30s, the particle model is too simple and makes predictions concerning relations among elastic moduli that are not met by experiment. Most of the subsequent development of this subject was in terms of the continuum theory. Controversies concerning the maximum possible number of independent elastic moduli in the most general anisotropic solid were settled by the British mathematician George Green in 1837. Green pointed out that the existence of an elastic strain energy

required that of the 36 elastic constants relating the 6 stress components to the 6 strains, at most 21 could be independent. The Scottish physicist Lord Kelvin put this consideration on sounder ground in 1855 as part of his development of macroscopic thermodynamics, showing that a strain energy function must exist for reversible isothermal or adiabatic (isentropic) response and working out such results as the (very modest) temperature changes associated with isentropic elastic deformation (see below *Thermodynamic considerations*).

Applications of elasticity

The middle and late 1800s were a period in which many basic elastic solutions were derived and applied to technology and to the explanation of natural phenomena. The French mathematician Adhémar-Jean-Claude Barré de Saint-Venant derived in the 1850s solutions for the torsion of noncircular cylinders, which explained the necessity of warping displacement of the cross section in the direction parallel to the axis of twisting, and for the flexure of beams due to transverse loadings; the latter allowed understanding of approximations inherent in the simple beam theory of Jakob Bernoulli, Euler, and Coulomb. The German physicist Heinrich Rudolf Hertz developed solutions for the deformation of elastic solids as they are brought into contact and applied these to model details of impact collisions. Solutions for stress and displacement due to concentrated forces acting at an interior point of a full space were derived by Kelvin, and those on the surface of a half space by the French mathematician Joseph Valentin Boussinesq and the Italian mathematician Valentino Cerruti. The Prussian mathematician Leo August Pochhammer analyzed the vibrations of an elastic cylinder, and Lamb and the Prussian physicist Paul Jaerisch derived the equations of general vibration of an elastic sphere in the 1880s, an effort that was continued by many seismologists in the 1900s to describe the vibrations of the Earth. In 1863 Kelvin had derived the basic form of the solution of the static elasticity equations for a spherical solid, and these were applied in following years to such problems as calculating the deformation of the Earth due to rotation and tidal forcing and measuring the effects of elastic deformability on the motions of the Earth's rotation axis.

The classical development of elasticity never fully confronted the problem of finite elastic straining, in which material fibres change their lengths by other than very small amounts. Possibly this was because the common materials of construction would remain elastic only for very small strains before exhibiting either plastic straining or brittle failure. However, natural polymeric materials show elasticity over a far wider range (usually also with enough time or rate effects that they would more accurately be characterized as viscoelastic), and the widespread use of natural rubber and similar materials motivated the development of finite elasticity. While many roots of the subject were laid in the classical theory, especially in the work of Green, Gabrio Piola, and Kirchhoff in the mid-1800s, the development of a viable theory with forms of stress-strain relations for specific rubbery elastic materials, as well as an understanding of the physical effects of the nonlinearity in simple problems such as torsion and bending, was mainly the achievement of the British-born engineer and applied mathematician Ronald S. Rivlin in the 1940s and '50s.

Waves. Poisson, Cauchy, and George G. Stokes showed that the equations of the general theory of elasticity predicted the existence of two types of elastic deformation waves which could propagate through isotropic elastic solids. These are called body waves. In the faster type, called longitudinal, dilational, or irrotational waves, the particle motion is in the same direction as that of wave propagation; in the slower type, called transverse, shear, or rotational waves, it is perpendicular to the propagation direction. No analogue of the shear wave exists for propagation through a fluid medium, and that fact led seismologists in the early 1900s to understand that the Earth has a liquid core (at the centre of which there is a solid inner core).

Lord Rayleigh showed in 1885 that there is a wave type that could propagate along surfaces, such that the motion associated with the wave decayed exponentially with distance into the material from the surface. This type of surface wave, now called a Rayleigh wave, propagates typically at slightly more than 90 percent of the shear wave speed and involves an elliptical path of particle motion that lies in planes parallel to that defined by the normal to the surface and the propagation direction. Another type of surface wave, with motion transverse to the propagation direction and parallel to the surface, was found by Love for solids in which a surface layer of material sits atop an elastically stiffer bulk solid; this defines the situation for the Earth's crust. The shaking in an earthquake is communicated first to distant places by body waves, but these spread out in three dimensions and to conserve the energy propagated by the wave field must diminish in their displacement amplitudes as r^{-1}, where r is the distance from the source. The surface waves spread out in only two dimensions and must, for the same reason, diminish only as fast as $r^{-1/2}$. Thus, the shaking effect of the surface waves from a crustal earthquake is normally felt more strongly, and is potentially more damaging, at moderate to large distances. Indeed, well before the theory of waves in solids was in hand, Thomas Young had suggested in his 1807 lectures on natural philosophy that the shaking of an earthquake "is probably propagated through the earth in the same manner as noise is conveyed through air." (It had been suggested by the American mathematician and astronomer John Winthrop, following his experience of the "Boston" earthquake of 1755, that the ground shaking was due to a disturbance propagated like sound through the air.)

Types of surface waves

With the development of ultrasonic transducers operated on piezoelectric principles, the measurement of the reflection and scattering of elastic waves has developed into an effective engineering technique for the nondestructive evaluation of materials for detection of such potentially dangerous defects as cracks. Also, very strong impacts, whether from meteorite collision, weaponry, or blasting and the like in technological endeavours, induce waves in which material response can be well outside the range of linear elasticity, involving any or all of finite elastic strain, plastic or viscoplastic response, and phase transformation. These are called shock waves; they can propagate much beyond the speed of linear elastic waves and are accompanied by significant heating.

Stress concentrations and fracture. In 1898 G. Kirsch derived the solution for the stress distribution around a circular hole in a much larger plate under remotely uniform tensile stress. The same solution can be adapted to the tunnellike cylindrical cavity of a circular section in a bulk solid. Kirsch's solution showed a significant concentration of stress at the boundary, by a factor of three when the remote stress was uniaxial tension. Then in 1907 the Russian mathematician Gury Vasilyevich Kolosov, and independently in 1914 the British engineer Charles Edward Inglis, derived the analogous solution for stresses around an elliptical hole. Their solution showed that the concentration of stress could become far greater, as the radius of curvature at an end of the hole becomes small compared with the overall length of the hole. These results provided the insight to sensitize engineers to the possibility of dangerous stress concentrations at sharp reentrant corners, notches, cutouts, keyways, screw threads, and similar openings in structures for which the nominal stresses were at otherwise safe levels. Such stress concentration sites are places from which a crack can nucleate.

The elliptical hole of Kolosov and Inglis defines a crack in the limit when one semimajor axis goes to zero, and the Inglis solution was adopted by the British aeronautical engineer A.A. Griffith in 1921 to describe a crack in a brittle solid. In that work Griffith made his famous proposition that a spontaneous crack growth would occur when the energy released from the elastic field just balanced the work required to separate surfaces in the solid. Following a hesitant beginning, in which Griffith's work was initially regarded as important only for very brittle solids such as glass, there developed, largely under the impetus of the American engineer and physicist George R. Irwin, a major body of work on the mechanics of crack growth and

Crack growth

fracture, including fracture by fatigue and stress corrosion cracking, starting in the late 1940s and continuing into the 1990s. This was driven initially by the cracking of a number of American Liberty ships during World War II, by the failures of the British Comet airplane, and by a host of reliability and safety issues arising in aerospace and nuclear reactor technology. The new complexion of the subject extended beyond the Griffith energy theory and, in its simplest and most widely employed version in engineering practice, used Irwin's stress intensity factor as the basis for predicting crack growth response under service loadings in terms of laboratory data that is correlated in terms of that factor. That stress intensity factor is the coefficient of a characteristic singularity in the linear elastic solution for the stress field near a crack tip; it is recognized as providing a proper characterization of crack tip stressing in many cases, even though the linear elastic solution must be wrong in detail near the crack tip owing to nonelastic material response, large strain, and discreteness of material microstructure.

Dislocations. The Italian elastician and mathematician Vito Volterra introduced in 1905 the theory of the elastostatic stress and displacement fields created by dislocating solids. This involves making a cut in a solid, displacing its surfaces relative to one another by some fixed amount, and joining the sides of the cut back together, filling in with material as necessary. The initial status of this work was simply regarded as an interesting way of generating elastic fields, but, in the early 1930s, Geoffrey Ingram Taylor, Egon Orowan, and Michael Polanyi realized that just such a process could be going on in ductile crystals and could provide an explanation of the low plastic shear strength of typical ductile solids, much as Griffith's cracks explained low fracture strength under tension. In this case, the displacement on the dislocated surface corresponds to one atomic lattice spacing in the crystal. It quickly became clear that this concept provided the correct microscopic description of metal plasticity, and, starting with Taylor in the 1930s and continuing into the 1990s, the use of solid mechanics to explore dislocation interactions and the microscopic basis of plastic flow in crystalline materials has been a major topic, with many distinguished contributors.

Microscopic description of plastic flow

The mathematical techniques advanced by Volterra are now in common use by earth scientists in explaining ground displacement and deformation induced by tectonic faulting. Also, the first elastodynamic solutions for the rapid motion of crystal dislocations, developed by South African materials scientist F.R.N. Nabarro in the early 1950s, were quickly adapted by seismologists to explain the radiation from propagating slip distributions on faults. The Japanese seismologist H. Nakano had already shown in 1923 how to represent the distant waves radiated by an earthquake as the elastodynamic response to a pair of force dipoles amounting to zero net torque. (All his manuscripts were destroyed in the fire in Tokyo associated with the great Kwanto earthquake in that same year, but copies of some had been sent to Western colleagues and the work survived.)

Continuum plasticity theory. The macroscopic theory of plastic flow has a history nearly as old as that of elasticity. While in the microscopic theory of materials, the word "plasticity" is usually interpreted as denoting deformation by dislocation processes, in macroscopic continuum mechanics it is taken to denote any type of permanent deformation of materials, especially those of a type for which time or rate of deformation effects are not the most dominant feature of the phenomenon (the terms viscoplasticity, creep, or viscoelasticity are usually used in such cases). Coulomb's work of 1773 on the frictional yielding of soils under shear and normal stress has been mentioned; yielding denotes the occurrence of large shear deformations without significant increase in applied stress. His results were used to explain the pressure of soils against retaining walls and footings in the work of the French mathematician and engineer Jean Victor Poncelet in 1840 and the Scottish engineer and physicist William John Macquorn Rankine in 1853. The inelastic deformation of soils and rocks often takes place in situations for which the deforming mass is infiltrated by groundwater, and Austrian-American civil engineer Karl Terzaghi in the 1920s developed the concept of effective stress, whereby the stresses that enter a criterion of yielding or failure are not the total stresses applied to the saturated soil or rock mass but rather the effective stresses, which are the difference between the total stresses and those of a purely hydrostatic stress state with pressure equal to that in the pore fluid. Terzaghi also introduced the concept of consolidation, in which the compression of a fluid-saturated soil can take place only as the fluid slowly flows through the pore space under pressure gradients, according to Darcy's law; this effect accounts for the time-dependent settlement of constructions over clay soils.

Apart from the earlier observation of plastic flow at large stresses in the tensile testing of bars, the theory of continuum plasticity for metallic materials begins with Henri Edouard Tresca in 1864. His experiments on the compression and indentation of metals led him to propose that this type of plasticity, in contrast to that in soils, was essentially independent of the average normal stress in the material and dependent only on shear stresses, a feature later rationalized by the dislocation mechanism. Tresca proposed a yield criterion for macroscopically isotropic metal polycrystals based on the maximum shear stress in the material, and that was used by Saint-Venant to solve an early elastic-plastic problem, that of the partly plastic cylinder in torsion, and also to solve for the stresses in a completely plastic tube under pressure.

Plane plastic flow

The German applied mechanician Ludwig Prandtl developed the rudiments of the theory of plane plastic flow in 1920 and 1921, with an analysis of indentation of a ductile solid by a flat-ended rigid indenter, and the resulting theory of plastic slip lines was completed by H. Hencky in 1923 and Hilda Geiringer in 1930. Additional developments include the methods of plastic limit analysis, which allowed engineers to directly calculate upper and lower bounds to the plastic collapse loads of structures or to forces required in metal forming. Those methods developed gradually over the early 1900s on a largely intuitive basis, first for simple beam structures and later for plates, and were put on a rigorous basis within the rapidly developing mathematical theory of plasticity about 1950 by Daniel C. Drucker and William Prager in the United States and Rodney Hill in Great Britain.

The Austrian-American applied mathematician Richard von Mises proposed in 1913 that a mathematically simpler theory of plasticity than that based on the Tresca yield criterion could be based on the second tensor invariant of the deviatoric stresses (*i.e.*, of the total stresses minus those of a hydrostatic state in which pressure is equal to the average normal stress over all planes). An equivalent yield criterion had been proposed independently by the Polish engineer Maksymilian Tytus Huber. The Mises theory incorporates a proposal by M. Levy in 1871 that components of the plastic strain increment tensor are in proportion to one another just as are the components of deviatoric stress. This criterion was generally found to provide slightly better agreement with experiment than did that of Tresca, and most work on the application of plasticity theory uses this form. Following a suggestion of Prandtl, E. Reuss completed the theory in 1930 by adding an elastic component of strain increments, related to stress increments in the same way as for linear elastic response. This formulation was soon generalized to include strain hardening, whereby the value of the second invariant for continued yielding increases with ongoing plastic deformation, and was extended to high-temperature creep response in metals or other hot solids by assuming that the second invariant of the plastic (now generally called "creep") strain rate is a function of that same invariant of the deviatoric stress, typically a power law type with Arrhenius temperature dependence.

Strain hardening

This formulation of plastic and viscoplastic, or creep, response has been applied to all manner of problems in materials and structural technology and in flow of geologic masses. Representative problems addressed include the growth and subsequent coalescence of microscopic voids in the ductile fracture of metals, the theory of the indentation hardness test, the extrusion of metal rods and

rolling of metal sheets, design against collapse of ductile steel structures, estimation of the thickness of the Greenland Ice Sheet, and modeling the geologic evolution of the Plateau of Tibet. Other types of elastic-plastic theories intended for analysis of ductile single crystals originate from the work of G.I. Taylor and Hill and base the criterion for yielding on E. Schmid's concept from the 1920s of a critical resolved shear stress along a crystal slip plane, in the direction of an allowed slip on that plane; this sort of yield condition has approximate support from the dislocation theory of plasticity.

Viscoelasticity. The German physicist Wilhelm Weber noticed in 1835 that a load applied to a silk thread produced not only an immediate extension but also a continuing elongation of the thread with time. This type of viscoelastic response is especially notable in polymeric solids but is present to some extent in all types of solids and often does not have a clear separation from what could be called viscoplastic, or creep, response. In general, if all of the strain is ultimately recovered when a load is removed from a body, the response is termed viscoelastic, but the term is also used in cases for which sustained loading leads to strains that are not fully recovered. The Austrian physicist Ludwig Boltzmann developed in 1874 the theory of linear viscoelastic stress-strain relations. In their most general form, these involve the notion that a step loading (a suddenly imposed stress that is subsequently maintained constant) causes an immediate strain followed by a time-dependent strain which, for different materials, either may have a finite limit at long time or may increase indefinitely with time. Within the assumption of linearity, the strain at time t in response to a general time-dependent stress history $\sigma(t)$ can then be written as the sum (or integral) of terms that involve the step-loading strain response due to a step loading $dt' d\sigma(t')/dt'$ at time t'. The theory of viscoelasticity is important for consideration of the attenuation of stress waves and the damping of vibrations.

Long-molecule polymers

A new class of problems arose with the mechanics of very-long-molecule polymers, which do not have significant cross-linking and exist either in solution or as a melt. These are fluids in the sense that they cannot long support shear stress, but at the same time they have remarkable properties like those of finitely deformed elastic solids. A famous demonstration is to pour one of these fluids slowly from a beaker and to cut the flowing stream suddenly with scissors; if the cut is not too far below the place of exit from the beaker, the stream of falling fluid immediately contracts elastically and returns to the beaker. The molecules are elongated during flow but tend to return to their thermodynamically preferred coiled configuration when forces are removed.

The theory of such materials came under intense development in the 1950s after the British applied mathematician James Gardner Oldroyd showed in 1950 how viscoelastic stress-strain relations of a memory type could be generalized to a flowing fluid. This requires that the constitutive relation, or rheological relation, between the stress history and the deformation history at a material "point" be properly invariant to a superposed history of rigid rotation, which should not affect the local physics determining that relation (the resulting Coriolis and centrifugal effects are quite negligible at the scale of molecular interactions). Important contributions on this issue were made by the applied mathematicians Stanisław Zaremba and Gustav Andreas Johannes Jaumann in the first decade of the 1900s; they showed how to make tensorial definitions of stress rate that were invariant to superposed spin and thus were suitable for use in constitutive relations. But it was only during the 1950s that these concepts found their way into the theory of constitutive relations for general viscoelastic materials; independently, a few years later, properly invariant stress rates were adopted in continuum formulations of elastic-plastic response.

Computational mechanics. The digital computer revolutionized the practice of many areas of engineering and science, and solid mechanics was among the first fields to benefit from its impact. Many computational techniques have been used in this field, but the one that emerged by the end of 1970s as, by far, the most widely adopted is the finite-element method. This method was outlined by the mathematician Richard Courant in 1943 and was developed independently, and put to practical use on computers, in the mid-1950s by the aeronautical structures engineers M.J. Turner, Ray W. Clough, Harold Clifford Martin, and LeRoy J. Topp in the United States and J.H. Argyris and Sydney Kelsey in Britain. Their work grew out of earlier attempts at systematic structural analysis for complex frameworks of beam elements. The method was soon recast in a variational framework and related to earlier efforts at deriving approximate solutions of problems described by variational principles. The new technique involved substituting trial functions of unknown amplitude into the variational functional, which is then rendered stationary as an algebraic function of the amplitude coefficients. In the most common version of the finite-element method, the domain to be analyzed is divided into cells, or elements, and the displacement field within each element is interpolated in terms of displacements at a few points around the element boundary (and sometimes within it) called nodes. The interpolation is done so that the displacement field is continuous across element boundaries for any choice of the nodal displacements. The strain at every point can thus be expressed in terms of nodal displacements, and it is then required that the stresses associated with these strains, through the stress-strain relations of the material, satisfy the principle of virtual work for arbitrary variation of the nodal displacements. This generates as many simultaneous equations as there are degrees of freedom in the finite element model, and numerical techniques for solving such systems of equations are programmed for computer solution.

Basic principles

Considerations in solid mechanics problems

In addressing any problem in continuum or solid mechanics, three factors must be considered: (1) the Newtonian equations of motion, in the more general form recognized by Euler, expressing conservation of linear and angular momentum for finite bodies (rather than just for point particles), and the related concept of stress, as formalized by Cauchy, (2) the geometry of deformation and thus the expression of strains in terms of gradients in the displacement field, and (3) the relations between stress and strain that are characteristic of the material in question, as well as of the stress level, temperature, and time scale of the problem considered.

These three considerations suffice for most problems. They must be supplemented, however, for solids undergoing diffusion processes in which one material constituent moves relative to another (which may be the case for fluid-infiltrated soils or petroleum reservoir rocks) and in cases for which the induction of a temperature field by deformation processes and the related heat transfer cannot be neglected. These cases require that the following also be considered: (4) equations for conservation of mass of diffusing constituents, (5) the first law of thermodynamics, which introduces the concept of heat flux and relates changes in energy to work and heat supply, and (6) relations that express the diffusive fluxes and heat flow in terms of spatial gradients of appropriate chemical potentials and of temperature. In many important technological devices, electric and magnetic fields affect the stressing, deformation, and motion of matter. Examples are provided by piezoelectric crystals and other ceramics for electric or magnetic actuators and by the coils and supporting structures of powerful electromagnets. In these cases, two more considerations must be added: (7) James Clerk Maxwell's set of equations interrelating electric and magnetic fields to polarization and magnetization of material media and to the density and motion of electric charge, and (8) augmented relations betweeen stress and strain, which now, for example, express all of stress, polarization, and magnetization in terms of strain, electric field, magnetic intensity, and temperature. The second law of thermodynamics, combined with the above-mentioned principles, serves to constrain physically allowed relations between stress, strain, and temperature in (3) and also

constrains the other types of relations described in (6) and (8) above. Such expressions, which give the relationships between stress, deformation, and other variables, are commonly referred to as constitutive relations.

Experimental determination of stress-strain relations

In general, the stress-strain relations are to be determined by experiment. A variety of mechanical testing machines and geometric configurations of material specimens have been devised to measure them. These allow, in different cases, simple tensile, compressive, or shear stressing, and sometimes combined stressing with several different components of stress, as well as the determination of material response over a range of temperatures, strain rates, and loading histories. The testing of round bars under tensile stress, with precise measurement of their extension to obtain the strain, is common for metals and for technological ceramics and polymers. For rocks and soils, which generally carry load in compression, the most common test involves a round cylinder that is compressed along its axis, often while being subjected to confining pressure on its curved face. Frequently, a measurement interpreted by solid mechanics theory is used to determine some of the properties entering stress-strain relations. For example, measuring the speed of deformation waves or the natural frequencies of vibration of structures can be used to extract the elastic moduli of materials of known mass density, and measurement of indentation hardness of a metal can be used to estimate its plastic shear strength.

In some favourable cases, stress-strain relations can be calculated approximately by applying principles of mechanics at the microscale of the material considered. In a composite material, the microscale could be regarded as the scale of the separate materials making up the reinforcing fibres and matrix. When their individual stress-strain relations are known from experiment, continuum mechanics principles applied at the scale of the individual constituents can be used to predict the overall stress-strain relations for the composite. For rubbery polymer materials, made up of long chain molecules that randomly configure themselves into coillike shapes, some aspects of the elastic stress-strain response can be obtained by applying principles of statistical thermodynamics to the partial uncoiling of the array of molecules by imposed strain. For a single crystallite of an element such as silicon or aluminum or for a simple compound like silicon carbide, the relevant microscale is that of the atomic spacing in the crystals; quantum mechanical principles governing atomic force laws at that scale can be used to estimate elastic constants. In the case of plastic flow processes in metals and in sufficiently hot ceramics, the relevant microscale involves the network of dislocation lines that move within crystals. These lines shift atom positions relative to one another by one atomic spacing as they move along slip planes. Important features of elastic-plastic and viscoplastic stress-strain relations can be understood by modeling the stress dependence of dislocation generation and motion and the resulting dislocation entanglement and immobilization processes that account for strain hardening.

To examine the mathematical structure of the theory, considerations (1) to (3) above will now be further developed. For this purpose, a continuum model of matter will be used, with no detailed reference to its discrete structure at molecular—or possibly other larger microscopic—scales far below those of the intended application.

LINEAR AND ANGULAR MOMENTUM PRINCIPLES: STRESS AND EQUATIONS OF MOTION

Let $\boldsymbol{x}$ denote the position vector of a point in space as measured relative to the origin of a Newtonian reference frame; $\boldsymbol{x}$ has the components (x_1, x_2, x_3) relative to a Cartesian set of axes, which is fixed in the reference frame and denoted as the 1, 2, and 3 axes in Figure 37. Suppose that a material occupies the part of space considered, and let $\boldsymbol{v} = \boldsymbol{v}(\boldsymbol{x}, t)$ be the velocity vector of the material point that occupies position $\boldsymbol{x}$ at time t; that same material point will be at position $\boldsymbol{x} + \boldsymbol{v}dt$ an infinitesimal interval dt later. Let $\rho = \rho(\boldsymbol{x}, t)$ be the mass density of the material. Here $\boldsymbol{v}$ and ρ are macroscopic variables. What is idealized in the continuum model as a material point, moving as a smooth function of time, will correspond on molecular-length (or larger but still "microscopic") scales to a region with strong fluctuations of density and velocity. In terms of phenomena at such scales, ρ corresponds to an average of mass per unit of volume, and $\rho\boldsymbol{v}$ to an average of linear momentum per unit volume, as taken over spatial and temporal scales that are large compared to those of the microscale processes but still small compared to those of the intended application or phenomenon under study. Thus, from the microscopic viewpoint, $\boldsymbol{v}$ of the continuum theory is a mass-weighted average velocity.

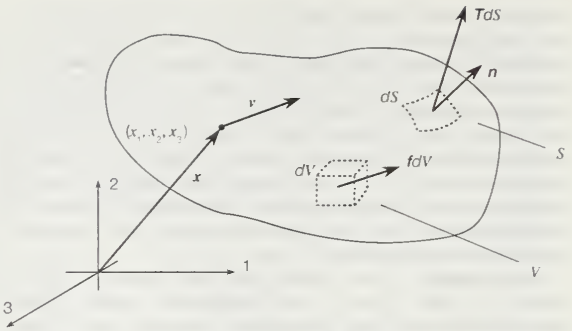

Figure 37: The position vector $\boldsymbol{x}$ and the velocity vector $\boldsymbol{v}$ of a material point, the body force $\boldsymbol{f}dV$ acting on an element dV of volume, and the surface force $\boldsymbol{T}dS$ acting on an element dS of surface in a Cartesian coordinate system 1, 2, 3 (see text).

The linear momentum $\boldsymbol{P}$ and angular momentum $\boldsymbol{H}$ (relative to the coordinate origin) of the matter instantaneously occupying any volume V of space are then given by summing up the linear and angular momentum vectors of each element of material. Such summation over infinitesimal elements is represented mathematically by the integrals $\boldsymbol{P} = \int_V \rho\boldsymbol{v}dV$ and $\boldsymbol{H} = \int_V \rho\boldsymbol{x} \times \boldsymbol{v}dV$. In this discussion attention is limited to situations in which relativistic effects can be ignored. Let $\boldsymbol{F}$ denote the total force and $\boldsymbol{M}$ the total torque, or moment (relative to the coordinate origin), acting instantaneously on the material occupying any arbitrary volume V. The basic laws of Newtonian mechanics are the linear and angular momentum principles that $\boldsymbol{F} = d\boldsymbol{P}/dt$ and $\boldsymbol{M} = d\boldsymbol{H}/dt$, where time derivatives of $\boldsymbol{P}$ and $\boldsymbol{H}$ are calculated following the motion of the matter that occupies V at time t. When either $\boldsymbol{F}$ or $\boldsymbol{M}$ vanishes, these equations of motion correspond to conservation of linear or angular momentum.

Static equilibrium problems

An important, very common, and nontrivial class of problems in solid mechanics involves determining the deformed and stressed configuration of solids or structures that are in static equilibrium; in that case the relevant basic equations are $\boldsymbol{F} = 0$ and $\boldsymbol{M} = 0$. The understanding of such conditions for equilibrium, at least in a rudimentary form, long predates Newton. Indeed, Archimedes of Syracuse (3rd century BC), the great Greek mathematician and arguably the first theoretically and experimentally minded physical scientist, understood these equations at least in a nonvectorial form appropriate for systems of parallel forces. This is shown by his treatment of the hydrostatic equilibrium of a partially submerged body and by his establishment of the principle of the lever (torques about the fulcrum sum to zero) and the concept of centre of gravity.

Stress. Assume that $\boldsymbol{F}$ and $\boldsymbol{M}$ derive from two types of forces, namely, body forces $\boldsymbol{f}$, such as gravitational attractions—defined such that force $\boldsymbol{f}dV$ acts on volume element dV (see Figure 37)—and surface forces, which represent the mechanical effect of matter immediately adjoining that along the surface S of the volume V being considered. Cauchy formalized in 1822 a basic assumption of continuum mechanics that such surface forces could be represented as a stress vector $\boldsymbol{T}$, defined so that $\boldsymbol{T}dS$ is an element of force acting over the area dS of the surface (Figure 37). Hence, the principles of linear and angular momentum take the forms

$$\int_S \boldsymbol{T}dS + \int_V \boldsymbol{f}dV = \boldsymbol{F} = \frac{d\boldsymbol{P}}{dt} = \int_V \rho\boldsymbol{a}dV, \text{ and} \qquad (111)$$

$$\int_S \boldsymbol{x} \times \boldsymbol{T}ds + \int_V \boldsymbol{x} \times \boldsymbol{f}dV = \boldsymbol{M} = \frac{d\boldsymbol{H}}{dt} = \int_V \rho\boldsymbol{x} \times \boldsymbol{a}dV, \qquad (112)$$

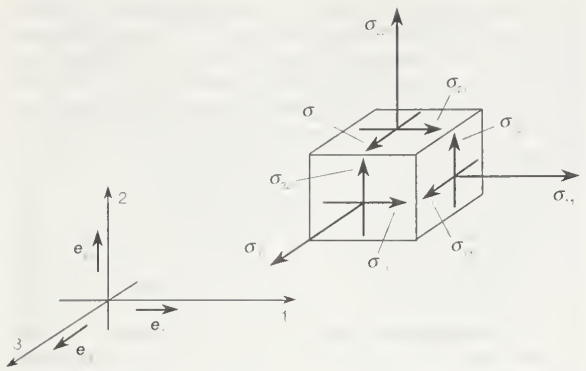

Figure 38: *The nine components of a stress tensor.* The first index denotes the direction of the normal, or perpendicular, stresses to the plane across which the contact force acts, and the second index denotes the direction of the component of force (see text).

which are now assumed to hold good for every conceivable choice of region V. In calculating the right-hand sides, which come from $d\boldsymbol{P}/dt$ and $d\boldsymbol{H}/dt$, it has been noted that ρdV is an element of mass and is therefore time-invariant; also, $\boldsymbol{a} = \boldsymbol{a}(\boldsymbol{x}, t) = d\boldsymbol{v}/dt$ is the acceleration, where the time derivative of $\boldsymbol{v}$ is taken following the motion of a material point so that $\boldsymbol{a}(\boldsymbol{x}, t)dt$ corresponds to the difference between $\boldsymbol{v}(\boldsymbol{x} + \boldsymbol{v}dt, t + dt)$ and $\boldsymbol{v}(\boldsymbol{x}, t)$. A more detailed analysis of this step shows that the understanding of what $\boldsymbol{T}dS$ denotes must now be adjusted to include averages, over temporal and spatial scales that are large compared to those of microscale fluctuations, of transfers of momentum across the surface S due to the microscopic fluctuations about the motion described by the macroscopic velocity $\boldsymbol{v}$.

The nine quantities $\sigma_{ij}(i, j = 1, 2, 3)$ are called stress components; these will vary with position and time—*i.e.*, $\sigma_{ij} = \sigma_{ij}(\boldsymbol{x}, t)$—and have the following interpretation. Consider an element of surface dS through a point $\boldsymbol{x}$ with dS oriented so that its outer normal (pointing away from the region V, bounded by S) points in the positive x_i direction, where i is any of 1, 2, or 3. Then σ_{i1}, σ_{i2}, and σ_{i3} at $\boldsymbol{x}$ are defined as the Cartesian components of the stress vector $\boldsymbol{T}$ (called $\boldsymbol{T}^{(i)}$) acting on this dS. Figure 38 shows the components of such stress vectors for faces in each of the three coordinate directions. To use a vector notation with $\boldsymbol{e}_1$, $\boldsymbol{e}_2$, and $\boldsymbol{e}_3$ denoting unit vectors along the coordinate axes (Figure 38), $\boldsymbol{T}^{(i)} = \sigma_{i1}\boldsymbol{e}_1 + \sigma_{i2}\boldsymbol{e}_2 + \sigma_{i3}\boldsymbol{e}_3$. Thus, the stress σ_{ij} at $\boldsymbol{x}$ is the stress in the j direction associated with an i-oriented face through point $\boldsymbol{x}$; the physical dimension of the σ_{ij} is [force]/[length]^2. The components σ_{11}, σ_{22}, and σ_{33} are stresses directed perpendicular, or normal, to the face on which they act and are normal stresses; the σ_{ij} with $i \neq j$ are directed parallel to the face on which they act and are shear stresses.

By hypothesis, the linear momentum principle applies for

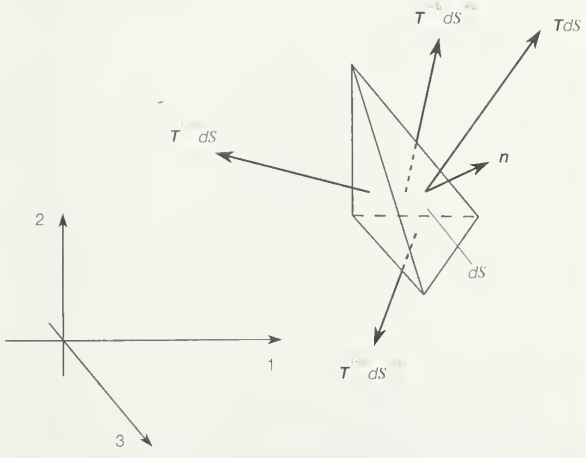

Figure 39: The force $\boldsymbol{T}dS$ acting on an arbitrarily inclined face (whose outward unit normal vector is $\boldsymbol{n}$). Stress vectors $\boldsymbol{T}^{(-1)}$, $\boldsymbol{T}^{(-2)}$, and $\boldsymbol{T}^{(-3)}$ act on the faces perpendicular to the coordinate axes.

any volume V. Consider a small tetrahedron (Figure 39) at $\boldsymbol{x}$ with an inclined face having an outward unit normal vector $\boldsymbol{n}$ and its other three faces oriented perpendicular to the three coordinate axes. Letting the size of the tetrahedron shrink to zero, the linear momentum principle requires that the stress vector $\boldsymbol{T}$ on a surface element with outward normal $\boldsymbol{n}$ be expressed as a linear function of the σ_{ij} at $\boldsymbol{x}$. The relation is such that the j component of the stress vector $\boldsymbol{T}$ is $T_j = n_1\sigma_{1j} + n_2\sigma_{2j} + n_3\sigma_{3j}$ for $(j = 1, 2, 3)$. This relation for $\boldsymbol{T}$ (or T_j) also demonstrates that the σ_{ij} have the mathematical property of being the components of a second-rank tensor.

Second-rank tensor

Suppose that a different set of Cartesian reference axes 1′, 2′, and 3′ have been chosen. Let x_1', x_2', and x_3' denote the components of the position vector of point $\boldsymbol{x}$ and let $\sigma_{kl}'(k, l = 1, 2, 3)$ denote the nine stress components relative to that coordinate system. The σ_{kl}' can be written as the 3×3 matrix $[\sigma']$, and the σ_{ij} as the matrix $[\sigma]$, where the first index is the matrix row number and the second is the column number. Then the expression for T_j implies that $[\sigma'] = [\alpha][\sigma][\alpha]^T$, which is the defining equation of a second-rank tensor. Here $[\alpha]$ is the orthogonal transformation matrix, having components $\alpha_{pq} = \boldsymbol{e}_p' \cdot \boldsymbol{e}_q$ for $p, q = 1, 2, 3$ and satisfying $[\alpha]^T[\alpha] = [\alpha][\alpha]^T = [I]$, where the superscript T denotes transpose (interchange rows and columns) and $[I]$ denotes the unit matrix, a 3×3 matrix with unity for every diagonal element and zero elsewhere; also, the matrix multiplications are such that if $[A] = [B][C]$, then $A_{ij} = B_{i1}C_{1j} + B_{i2}C_{2j} + B_{i3}C_{3j}$.

Equations of motion. Now the linear momentum principle may be applied to an arbitrary finite body. Using the expression for T_j above and the divergence theorem of multivariable calculus, which states that integrals over the area of a closed surface S, with integrand $n_i f(\boldsymbol{x})$, may be rewritten as integrals over the volume V enclosed by S, with integrand $\partial f(\boldsymbol{x})/\partial x_i$, when $f(\boldsymbol{x})$ is a differentiable function, one may derive that

$$\frac{\partial \sigma_{1j}}{\partial x_1} + \frac{\partial \sigma_{2j}}{\partial x_2} + \frac{\partial \sigma_{3j}}{\partial x_3} + f_j = \rho a_j \quad (j = 1, 2, 3), \tag{113}$$

at least when the σ_{ij} are continuous and differentiable, which is the typical case. These are the equations of motion for a continuum. Once the above consequences of the linear momentum principle are accepted, the only further result that can be derived from the angular momentum principle is that $\sigma_{ij} = \sigma_{ji}$ $(i, j = 1, 2, 3)$. Thus, the stress tensor is symmetric.

Principal stresses. Symmetry of the stress tensor has the important consequence that, at each point $\boldsymbol{x}$, there exist three mutually perpendicular directions along which there are no shear stresses. These directions are called the principal stress directions, and the corresponding normal stresses are called the principal stresses. If the principal stresses are ordered algebraically as σ_{I}, σ_{II}, and σ_{III} (Figure 40), then the normal stress on any face (given as $\sigma_n = \boldsymbol{n} \cdot \boldsymbol{T}$) satisfies $\sigma_{\mathrm{I}} \leq \sigma_n \leq \sigma_{\mathrm{III}}$. The principal stresses are the eigenvalues (or characteristic values) s, and the principal directions the eigenvectors $\boldsymbol{n}$, of the problem $\boldsymbol{T} = s\boldsymbol{n}$, or $[\sigma]\{n\} = s\{n\}$ in matrix notation with the 3-column $\{n\}$ representing $\boldsymbol{n}$. It has solutions when $\det([\sigma] - s[I]) = -s^3 + I_1 s^2 + I_2 s + I_3 = 0$, with $I_1 = \mathrm{tr}[\sigma]$, $I_2 = -(1/2)I_1^2 + (1/2)\mathrm{tr}([\sigma][\sigma])$, and $I_3 = \det[\sigma]$. Here "det" denotes determinant and "tr" denotes trace, or sum of diagonal elements, of a matrix. Since the principal stresses are determined by I_1, I_2, and I_3 and can have no dependence on how one chooses the coordinate system with respect to which the components of stress are referred, I_1, I_2, and I_3 must be independent of that choice and are therefore called stress invariants. One may readily verify that they have the same values when evaluated in terms of σ_{ij}' above as in terms of σ_{ij} by using the tensor transformation law and properties noted for the orthogonal transformation matrix.

Stress invariants

Very often, in both nature and technology, there is interest in structural elements in forms that might be identified as strings, wires, rods, bars, beams, or columns, or as membranes, plates, or shells. These are usually idealized as, respectively, one- or two-dimensional continua. One possible approach is then to develop the consequences

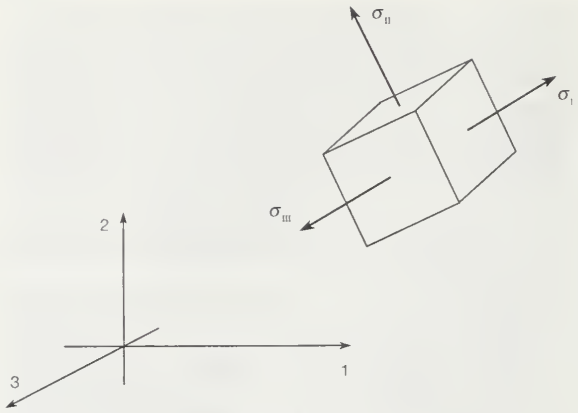

Figure 40: Principal stresses (see text).

of the linear and angular momentum principles entirely within that idealization, working in terms of net axial and shear forces and bending and twisting torques at each point along a one-dimensional continuum, or in terms of forces and torques per unit length of surface in a two-dimensional continuum.

GEOMETRY OF DEFORMATION

Strain and strain-displacement relations. The shape of a solid or structure changes with time during a deformation process. To characterize deformation, or strain, a certain reference configuration is adopted and called undeformed. Often, that reference configuration is chosen as an unstressed state, but such is neither necessary nor always convenient. If time is measured from zero at a moment when the body exists in that reference configuration, then the upper case $\boldsymbol{X}$ may be used to denote the position vectors of material points when $t = 0$. At some other time t, a material point that was at $\boldsymbol{X}$ will have moved to some spatial position $\boldsymbol{x}$. The deformation is thus described as the mapping $\boldsymbol{x} = \boldsymbol{x}(\boldsymbol{X}, t)$, with $\boldsymbol{x} = \boldsymbol{x}(\boldsymbol{X}, 0) = \boldsymbol{X}$. The displacement vector $\boldsymbol{u}$ is then $\boldsymbol{u} = \boldsymbol{x}(\boldsymbol{X}, t) - \boldsymbol{X}$; also, $\boldsymbol{v} = \partial \boldsymbol{x}(\boldsymbol{X}, t)/\partial t$ and $\boldsymbol{a} = \partial^2 \boldsymbol{x}(\boldsymbol{X}, t)/\partial t^2$.

It is simplest to write equations for strain in a form that, while approximate in general, is suitable for the case when any infinitesimal line element $d\boldsymbol{X}$ of the reference configuration undergoes extremely small rotations and fractional change in length, in deforming to the corresponding line element $d\boldsymbol{x}$. These conditions are met when $|\partial u_i/\partial X_j| << 1$. Many solids are often sufficiently rigid, at least under the loadings typically applied to them, that these conditions are realized in practice. Linearized expressions for strain in terms of $[\partial u/\partial X]$, appropriate to this situation, are called small strain or infinitesimal strain. Expressions for strain will also be given that are valid for rotations and fractional length changes of arbitrary magnitude; such expressions are called finite strain.

Two simple types of strain are extensional strain and shear strain. Consider a rectangular parallelepiped, a brick-like block of material with mutually perpendicular planar faces, and let the edges of the block be parallel to the 1, 2, and 3 axes. If the block is deformed homogeneously, so that each planar face moves perpendicular to itself and so that the faces remain orthogonal (*i.e.*, the parallelepiped is deformed into another rectangular parallelepiped), then the block is said to have undergone extensional strain relative to each of the 1, 2, and 3 axes but no shear strain relative to these axes. If the edge lengths of the undeformed parallelepiped are denoted as ΔX_1, ΔX_2, and ΔX_3, and those of the deformed parallelepiped as Δx_1, Δx_2, and Δx_3 (see Figure 41A, where the dashed-line figure represents the reference configuration and the solid-line figure the deformed configuration), then the quantities $\lambda_1 = \Delta x_1/\Delta X_1$, $\lambda_2 = \Delta x_2/\Delta X_2$, and $\lambda = \Delta x_3/\Delta X_3$ are called stretch ratios. There are various ways that extensional strain can be defined in terms of them. Note that the change in displacement in, say, the x_1 direction between points at one end of the block and those at the other is $\Delta u_1 = (\lambda_1 - 1)\Delta X_1$. For example, if E_{11} denotes the extensional strain along the x_1 direction, then the most commonly understood definition of strain is E_{11} = (change in length)/(initial length) = $(\Delta x_1 - \Delta X_1)/\Delta X_1 = \Delta u_1/\Delta X_1 = \lambda_1 - 1$. A variety of other measures of extensional strain can be defined by $E_{11} = g(\lambda_1)$, where the function $g(\lambda)$ satisfies $g(1) = 0$ and $g'(1) = 1$, so as to agree with the above definition when λ_1 is very near 1. Two such measures in common use are the strain $E_{11}^{M} = (\lambda_1^2 - 1)/2$, based on the change of metric tensor, and the logarithmic strain $E_{11}^{L} = \ln(\lambda_1)$.

Simple shear strain

To define a simple shear strain, consider the same rectangular parallelepiped, but now deform it so that every point on a plane of type X_2 = constant moves only in the x_1 direction by an amount that increases linearly with X_2. Thus, the deformation $x_1 = \gamma X_2 + X_1$, $x_2 = X_2$, $x_3 = X_3$ defines a homogeneous simple shear strain of amount γ and is illustrated in Figure 41B. Note that this strain causes no change of volume. For small strain, the shear strain γ can be identified as the reduction in angle between two initially perpendicular lines.

Small-strain tensor. The small strains, or infinitesimal strains, ε_{ij} are appropriate for situations with $|\partial u_k/\partial X_l| << 1$ for all k and l. Two infinitesimal material fibres, one initially in the 1 direction and the other in the 2 direction, are shown in Figure 42 as dashed lines in the reference configuration and as solid lines in the deformed configuration. To first-order accuracy in components of $[\partial u/\partial X]$, the extensional strains of these fibres are $\varepsilon_{11} = \partial u_1/\partial X_1$ and $\varepsilon_{22} = \partial u_2/\partial X_2$, and the reduction of the angle between them is $\gamma_{12} = \partial u_2/\partial X_1 + \partial u_1/\partial X_2$. For the shear strain denoted ε_{12}, however, half of γ_{12} is used. Thus, considering all extensional and shear strains associated with infinitesimal fibres in the 1, 2, and 3 directions at a point of the material, the set of strains is given by

$$\varepsilon_{ij} = \frac{1}{2}\left(\frac{\partial u_j}{\partial X_i} + \frac{\partial u_i}{\partial X_j}\right) \qquad (i, j = 1, 2, 3). \tag{114}$$

The ε_{ij} are symmetric—*i.e.*, $\varepsilon_{ij} = \varepsilon_{ji}$—and form a second-rank tensor (that is, if Cartesian reference axes 1′, 2′, and 3′ were chosen instead and the ε_{kl}' were determined, then the ε_{kl}' are related to the ε_{ij} by the same equations that relate the stresses σ_{kl}' to the σ_{ij}). These mathematical features require that there exist principal strain directions; at every point of the continuum it is possible to identify three mutually perpendicular directions along which there is purely extensional strain, with no shear strain between these special directions. The directions are the principal strain directions, and the corresponding strains include the least and greatest extensional strains experienced by fibres through the material point considered. Invariants of the

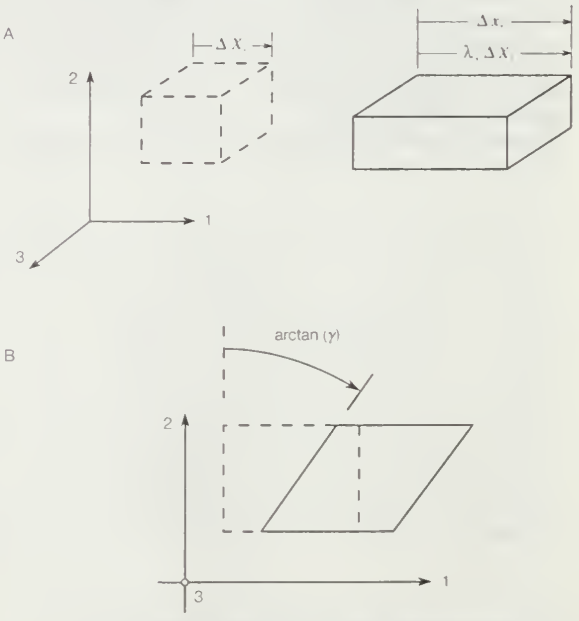

Figure 41: (A) Extensional strain and (B) simple shear strain, where the element drawn with dashed lines represents the reference configuration and the element drawn with solid lines represents the deformed configuration.

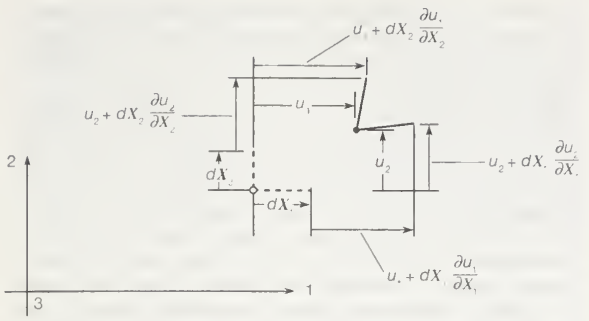

Figure 42: Relations of strains to gradients of displacement (see text).

strain tensor may be defined in a way paralleling those for the stress tensor.

An important fact to note is that the strains cannot vary in an arbitrary manner from point to point in the body. This is because the six strain components are all derivable from three displacement components. Restrictions on strain resulting from such considerations are called compatibility relations; the body would not fit together after deformation unless they were satisfied. Consider, for example, a state of plane strain in the 1, 2 plane (so that $\varepsilon_{33} = \varepsilon_{23} = \varepsilon_{31} = 0$). The nonzero strains ε_{11}, ε_{22}, and ε_{12} cannot vary arbitrarily from point to point but must satisfy $\partial^2\varepsilon_{22}/\partial X_1^2 + \partial^2\varepsilon_{11}/\partial X_2^2 = 2\partial^2\varepsilon_{12}/\partial X_1 \partial X_2$, as may be verified by directly inserting the relations for strains in terms of displacements.

Compatibility restrictions

When the smallness of stretch and rotation of line elements allows use of the infinitesimal strain tensor, a derivative $\partial/\partial X_i$ will be very nearly identical to $\partial/\partial x_i$. Frequently, but not always, it will then be acceptable to ignore the distinction between the deformed and undeformed configurations in writing the governing equations of solid mechanics. For example, the differential equations of motion in terms of stress are rigorously correct only with derivatives relative to the deformed configuration, but, in the circumstances considered, the equations of motion can be written relative to the undeformed configuration. This is what is done in the most widely used variant of solid mechanics, in the form of the theory of linear elasticity. The procedure can be unsatisfactory and go badly wrong in some important cases, however, such as for columns that buckle under compressive loadings or for elastic-plastic materials when the slope of the stress versus strain relation is of the same order as existing stresses. Cases such as these are instead best approached through finite deformation theory.

Finite deformation and strain tensors. In the theory of finite deformations, extension and rotations of line elements are unrestricted as to size. For an infinitesimal fibre that deforms from an initial point given by the vector dX to the vector dx in the time t, the deformation gradient is defined by $F_{ij} = \partial x_i(X, t)/\partial X_j$; the 3×3 matrix $[F]$, with components F_{ij}, may be represented as a pure deformation, characterized by a symmetric matrix $[U]$, followed by a rigid rotation $[R]$. This result is called the polar decomposition theorem and takes the form, in matrix notation, $[F] = [R][U]$. For an arbitrary deformation, there exist three mutually orthogonal principal stretch directions at each point of the material; call these directions in the reference configuration $N^{(I)}$, $N^{(II)}$, $N^{(III)}$, and let the stretch ratios be λ_I, λ_{II}, λ_{III}. Fibres in these three principal strain directions undergo extensional strain but have no shearing between them. Those three fibres in the deformed configuration remain orthogonal but are rotated by the operation $[R]$.

As noted earlier, an extensional strain may be defined by $E = g(\lambda)$, where $g(1) = 0$ and $g'(1) = 1$, with examples for $g(\lambda)$ given above. A finite strain tensor E_{ij} may then be defined based on any particular function $g(\lambda)$ by $E_{ij} = g(\lambda_I)N_i^{(I)}N_j^{(I)} + g(\lambda_{II})N_i^{(II)}N_j^{(II)} + g(\lambda_{III})N_i^{(III)}N_j^{(III)}$. Usually, it is rather difficult to actually solve for the λ's and N's associated with any general $[F]$, so it is not easy to use this strain definition. However, for the special choice identified as $g^M(\lambda) = (\lambda^2 - 1)/2$ above, it may be shown that $2E_{ij}^M = \sum_{k=1}^{3} F_{ki}F_{kj} - \delta_{ij} = \partial u_i/\partial X_j + \partial u_j/\partial X_i + \sum_{k=1}^{3} (\partial u_k/\partial X_i)(\partial u_k/\partial X_j)$, which, like the finite strain generated by any other $g(\lambda)$, reduces to ε_{ij} when linearized in $[\partial u/\partial X]$.

STRESS-STRAIN RELATIONS

Linear elastic isotropic solid. The simplest type of stress-strain relation is that of the linear elastic solid, considered in circumstances for which $|\partial u_i/\partial X_j| << 1$ and for isotropic materials, whose mechanical response is independent of the direction of stressing. If a material point sustains a stress state $\sigma_{11} = \sigma$, with all other $\sigma_{ij} = 0$, it is subjected to uniaxial tensile stress. This can be realized in a homogeneous bar loaded by an axial force. The resulting strain may be rewritten as $\varepsilon_{11} = \sigma/E$, $\varepsilon_{22} = \varepsilon_{33} = -\nu\varepsilon_{11} = -\nu\sigma/E$, $\varepsilon_{12} = \varepsilon_{23} = \varepsilon_{31} = 0$. Two new parameters have been introduced here, E and ν. E is called Young's modulus, and it has dimensions of [force]/[length]^2 and is measured in units such as the pascal (1 Pa = 1 N/m^2), dyne/cm^2, or pounds per square inch (psi); ν, which equals the ratio of lateral strain to axial strain, is dimensionless and is called the Poisson ratio.

Young's modulus

If the isotropic solid is subjected only to shear stress τ—*i.e.*, $\sigma_{12} = \sigma_{21} = \tau$, with all other $\sigma_{ij} = 0$—then the response is shearing strain of the same type, $\varepsilon_{12} = \tau/2G$, $\varepsilon_{23} = \varepsilon_{31} = \varepsilon_{11} = \varepsilon_{22} = \varepsilon_{33} = 0$. Notice that because $2\varepsilon_{12} = \gamma_{12}$, this is equivalent to $\gamma_{12} = \tau/G$. The constant G introduced is called the shear modulus. (Frequently, the symbol μ is used instead of G.) The shear modulus G is not independent of E and ν but is related to them by $G = E/2(1 + \nu)$, as follows from the tensor nature of stress and strain. The general stress-strain relations are then

$$\varepsilon_{ij} = (1 + \nu)\frac{\sigma_{ij}}{E} - \nu\delta_{ij}\frac{\sigma_{11} + \sigma_{22} + \sigma_{33}}{E} \qquad (i, j = 1, 2, 3), \tag{115}$$

where δ_{ij} is defined as 1 when its indices agree and 0 otherwise.

These relations can be inverted to read $\sigma_{ij} = \lambda\delta_{ij}(\varepsilon_{11} + \varepsilon_{22} + \varepsilon_{33}) + 2\mu\varepsilon_{ij}$, where μ has been used rather than G as the notation for the shear modulus, following convention, and where $\lambda = 2\nu\mu/(1 - 2\nu)$. The elastic constants λ and μ are sometimes called the Lamé constants. Since ν is typically in the range 1/4 to 1/3 for hard polycrystalline solids, λ falls often in the range between μ and 2μ. (Navier's particle model with central forces leads to $\lambda = \mu$ for an isotropic solid.)

Another elastic modulus often cited is the bulk modulus K, defined for a linear solid under pressure $p(\sigma_{11} = \sigma_{22} = \sigma_{33} = -p)$ such that the fractional decrease in volume is p/K. For example, consider a small cube of side length L in the reference state. If the length along, say, the 1 direction changes to $(1 + \varepsilon_{11})L$, the fractional change of volume is $(1 + \varepsilon_{11})(1 + \varepsilon_{22})(1 + \varepsilon_{33}) - 1 = \varepsilon_{11} + \varepsilon_{22} + \varepsilon_{33}$, neglecting quadratic and cubic order terms in the ε_{ij} compared to the linear, as is appropriate when using linear elasticity. Thus, $K = E/3(1 - 2\nu) = \lambda + 2\mu/3$.

Thermal strains. Temperature change can also cause strain. In an isotropic material the thermally induced extensional strains are equal in all directions, and there are no shear strains. In the simplest cases, these thermal strains can be treated as being linear in the temperature change $\theta - \theta_0$ (where θ_0 is the temperature of the reference state), writing $\varepsilon_{ij}^{thermal} = \delta_{ij}\alpha(\theta - \theta_0)$ for the strain produced by temperature change in the absence of stress. Here α is called the coefficient of thermal expansion. Thus, in cases of temperature change, ε_{ij} is replaced in the stress-strain relations above with $\varepsilon_{ij} - \varepsilon_{ij}^{thermal}$, with the thermal part given as a function of temperature. Typically, when temperature changes are modest, the small dependence of E and ν on temperature can be neglected.

Anisotropy. Anisotropic solids also are common in nature and technology. Examples are single crystals; polycrystals in which the grains are not completely random in their crystallographic orientation but have a "texture," typically owing to some plastic or creep flow process that has left a preferred grain orientation; fibrous biological materials such as wood or bone; and composite materials that, on a

microscale, either have the structure of reinforcing fibres in a matrix, with fibres oriented in a single direction or in multiple directions (*e.g.*, to ensure strength along more than a single direction), or have the structure of a lamination of thin layers of separate materials. In the most general case, the application of any of the six components of stress induces all six components of strain, and there is no shortage of elastic constants. There would seem to be $6 \times 6 = 36$ in the most general case, but, as a consequence of the laws of thermodynamics, the maximum number of independent elastic constants is 21 (compared with 2 for isotropic solids). In many cases of practical interest, symmetry considerations reduce the number to far below 21. For example, crystals of cubic symmetry, such as rock salt (NaCl); face-centred cubic metals, such as aluminum, copper, or gold; body-centred cubic metals, such as iron at low temperatures or tungsten; and such nonmetals as diamond, germanium, or silicon have only three independent elastic constants. Solids with a special direction, and with identical properties along any direction perpendicular to that direction, are called transversely isotropic; they have five independent elastic constants. Examples are provided by fibre-reinforced composite materials, with fibres that are randomly emplaced but aligned in a single direction in an isotropic or transversely isotropic matrix, and by single crystals of hexagonal close packing such as zinc.

Transversely isotropic solids

General linear elastic stress-strain relations have the form $\sigma_{ij} = \sum_{k=1}^{3} \sum_{l=1}^{3} C_{ijkl} \varepsilon_{kl}$, where the coefficients C_{ijkl} are known as the tensor elastic moduli. Because the ε_{kl} are symmetric, one may choose $C_{ijkl} = C_{ijlk}$, and, because the σ_{ij} are symmetric, $C_{ijkl} = C_{jikl}$. Hence the $3 \times 3 \times 3 \times 3 = 81$ components of C_{ijkl} reduce to the $6 \times 6 = 36$ mentioned. In cases of temperature change, the ε_{ij} above is replaced by $\varepsilon_{ij} - \varepsilon_{ij}^{thermal}$, where $\varepsilon_{ij}^{thermal} = \alpha_{ij}(\theta - \theta_0)$ and α_{ij} is the set of thermal strain coefficients, with $\alpha_{ij} = \alpha_{ji}$. An alternative matrix notation is sometimes employed, especially in the literature on single crystals. That approach introduces 6-element columns of stress and strain $\{\sigma\}$ and $\{\varepsilon\}$, defined so that the columns, when transposed (superscript T) or laid out as rows, are $\{\sigma\}^T = (\sigma_{11}, \sigma_{22}, \sigma_{33}, \sigma_{12}, \sigma_{23}, \sigma_{31})$ and $\{\varepsilon\}^T = (\varepsilon_{11}, \varepsilon_{22}, \varepsilon_{33}, 2\varepsilon_{12}, 2\varepsilon_{23}, 2\varepsilon_{31})$. These forms assure that the scalar $\{\sigma\}^T\{d\varepsilon\} \equiv \mathrm{tr}([\sigma][d\varepsilon])$ is an increment of stress working per unit volume. The stress-strain relations are then written $\{\sigma\} = [c]\{\varepsilon\}$, where $[c]$ is the 6×6 matrix of elastic moduli. Thus, $c_{13} = C_{1133}$, $c_{15} = C_{1123}$, $c_{44} = C_{1212}$, and so on.

Thermodynamic considerations. In thermodynamic terminology, a state of purely elastic material response corresponds to an equilibrium state, and a process during which there is purely elastic response corresponds to a sequence of equilibrium states and hence to a reversible process. The second law of thermodynamics assures that the heat absorbed per unit mass can be written θds, where θ is the thermodynamic (absolute) temperature and s is the entropy per unit mass. Hence, writing the work per unit volume of reference configuration in a manner appropriate to cases when infinitesimal strain can be used, and letting ρ_0 be the density in that configuration, from the first law of thermodynamics it can be stated that $\rho_0 \theta ds + \mathrm{tr}([\sigma][d\varepsilon]) = \rho_0 de$, where e is the internal energy per unit mass. This relation shows that if e is expressed as a function of entropy s and strains $[\varepsilon]$, and if e is written so as to depend identically on ε_{ij} and ε_{ji}, then $\sigma_{ij} = \rho_0 \partial e([\varepsilon], s)/\partial \varepsilon_{ij}$.

Helmholtz free energy

Alternatively, one may introduce the Helmholtz free energy f per unit mass, where $f = e - \theta s = f([\varepsilon], \theta)$, and show that $\sigma_{ij} = \rho_0 \partial f([\varepsilon], \theta)/\partial \varepsilon_{ij}$. The latter form corresponds to the variables with which the stress-strain relations were written above. Sometimes $\rho_0 f$ is called the strain energy for states of isothermal (constant θ) elastic deformation; $\rho_0 e$ has the same interpretation for isentropic (s = constant) elastic deformation, achieved when the time scale is too short to allow heat transfer to or from a deforming element. Since the mixed partial derivatives must be independent of order, a consequence of the last equation is that $\partial \sigma_{ij}([\varepsilon], \theta)/\partial \varepsilon_{kl} = \partial \sigma_{kl}([\varepsilon], \theta)/\partial \varepsilon_{ij}$, which requires that $C_{ijkl} = C_{klij}$, or equivalently that the matrix $[c]$ be symmetric, $[c] = [c]^T$, reducing the maximum possible number of independent elastic constraints from 36 to 21. The strain energy $W([\varepsilon])$ at constant temperature θ_0 is $W([\varepsilon]) \equiv \rho_0 f([\varepsilon], \theta_0) = (1/2)\{\varepsilon\}^T[c]\{\varepsilon\}$.

The elastic moduli for isentropic response are slightly different from those for isothermal response. In the case of the isotropic material, it is convenient to give results in terms of G and K, the isothermal shear and bulk moduli. The isentropic moduli $\overline{G}$ and $\overline{K}$ are then $\overline{G} = G$ and $\overline{K} = K(1 + 9\theta_0 K \alpha^2/\rho_0 c_\varepsilon)$, where $c_\varepsilon = \theta_0 \partial s([\varepsilon], \theta)/\partial \theta$, evaluated at $\theta = \theta_0$ and $[\varepsilon] = [0]$, is the specific heat at constant strain. The fractional change in the bulk modulus, given by the second term in the parentheses, is very small, typically on the order of 1 percent or less, even for metals and ceramics of relatively high α, on the order of 10^{-5}/kelvin.

The fractional change in absolute temperature during an isentropic deformation is found to involve the same small parameter: $[(\theta - \theta_0)/\theta_0]_{s = \text{const}} = -(9\theta_0 K \alpha^2/\rho_0 c_\varepsilon)[(\varepsilon_{11} + \varepsilon_{22} + \varepsilon_{33})/3\alpha\theta_0]$. Values of α for most solid elements and inorganic compounds are in the range of 10^{-6} to 4×10^{-5}/kelvin; room temperature is about 300 kelvins, so $3\alpha\theta_0$ is typically in the range 10^{-3} to 4×10^{-2}. Thus, if the fractional change in volume is on the order of 1 percent, which is quite large for a metal or ceramic deforming in its elastic range, the fractional change in absolute temperature is also on the order of 1 percent. For those reasons, it is usually appropriate to neglect the alteration of the temperature field due to elastic deformation and hence to use purely mechanical formulations of elasticity in which distinctions between isentropic and isothermal response are neglected.

Finite elastic deformations. When elastic response under arbitrary deformation gradients is considered—because rotations, if not strains, are large or, in a material such as rubber, because the strains are large too—it is necessary to dispense with the infinitesimal strain theory. In such cases, the combined first and second laws of thermodynamics have the form $\rho_0 \theta ds + \det[F]\mathrm{tr}([F]^{-1}[\sigma][dF]) = \rho_0 de$, where $[F]^{-1}$ is the matrix inverse of the deformation gradient $[F]$. If a parcel of material is deformed by $[F]$ and then given some additional rigid rotation, the free energy f must be unchanged in that rotation. In terms of the polar decomposition $[F] = [R][U]$, this is equivalent to saying that f is independent of the rotation part $[R]$ of $[F]$, which is then equivalent to saying that f is a function of the finite strain measure $[E^M] = (1/2)([F]^T[F] - [I])$ based on change of metric or, for that matter, on any member of the family of material strain tensors. Thus,

$$\sigma_{ij} = (1/\det[F]) \sum_{k=1}^{3} \sum_{l=1}^{3} F_{ik} F_{jl} S_{kl}([E^M], \theta]), \text{ where } S_{kl} (= S_{lk})$$

Piola-Kirchhoff stress

is sometimes called the second Piola-Kirchhoff stress and is given by $S_{kl} = \rho_0 \partial f([E^M], \theta)/\partial E^M_{kl}$, it being assumed that f has been written so as to have identical dependence on E^M_{kl} and E^M_{lk}.

Inelastic response. The above mode of expressing $[\sigma]$ in terms of $[S]$ is valid for solids showing viscoelastic or plastic response as well, except that $[S]$ is then to be regarded not only as a function of the present $[E^M]$ and θ but also as dependent on the prior history of both. Assuming that such materials show elastic response to sudden stress changes or to small unloading from a plastically deforming state, $[S]$ may still be expressed as a derivative of f, as above, but the derivative is understood as being taken with respect to an elastic variation of strain and is to be taken at fixed θ and with fixed prior inelastic deformation and temperature history. Such dependence on history is sometimes represented as a dependence of f on internal state variables whose laws of evolution are part of the inelastic constitutive description. There are also simpler models of inelastic response, and the most commonly employed forms for plasticity and creep in isotropic solids are presented next.

To a good approximation, plastic deformation of crystalline solids causes no change in volume; and hydrostatic changes in stress, amounting to equal change of all normal stresses, have no effect on plastic flow, at least for changes that are of the same order or magnitude as the strength

of the solid in shear. Thus, plastic response is usually formulated in terms of deviatoric stress, which is defined by $\tau_{ij} = \sigma_{ij} - \delta_{ij}(\sigma_{11} + \sigma_{22} + \sigma_{33})/3$. Following Richard von Mises, in a procedure that is found to agree moderately well with experiment, the plastic flow relation is formulated in terms of the second invariant of deviatoric stress, commonly rewritten as $\bar{\sigma} = \sqrt{(3/2)\mathrm{tr}([\tau][\tau])}$ and called the

Equivalent tensile stress

equivalent tensile stress. The definition is made so that, for a state of uniaxial tension, $\bar{\sigma}$ equals the tensile stress, and the stress-strain relation for general stress states is formulated in terms of data from the tensile test. In particular, a plastic strain $\bar{\varepsilon}^p$ in a uniaxial tension test is defined from $\bar{\varepsilon}^p = \bar{\varepsilon} - \bar{\sigma}/E$, where $\bar{\varepsilon}$ is interpreted as the strain in the tensile test according to the logarithmic definition $\bar{\varepsilon} = \ln\lambda$, the elastic modulus E is assumed to remain unchanged with deformation, and $\bar{\sigma}/E << 1$.

Thus, in the rate-independent plasticity version of the theory, tensile data (or compressive, with appropriate sign reversals) from a monotonic load test is assumed to define a function $\bar{\varepsilon}^p(\bar{\sigma})$. In the viscoplastic or high-temperature creep versions of the theory, tensile data is interpreted to define $d\bar{\varepsilon}^p/dt$ as a function of $\bar{\sigma}$ in the simplest case, representing, for example, secondary creep, and as a function of $\bar{\sigma}$ and $\bar{\varepsilon}^p$ in theories intended to represent transient creep effects or rate-sensitive response at lower temperatures. Consider first the rigid-plastic material model in which elastic deformability is ignored altogether, as is sometimes appropriate for problems of large plastic flow, as in metal forming or long-term creep in the Earth's mantle or for analysis of plastic collapse loads on structures. The rate of deformation tensor D_{ij} is defined by $2D_{ij} = \partial v_i/\partial x_j + \partial v_j/\partial x_i$, and in the rigid-plastic case $[D]$ can be equated to what may be considered its plastic part $[D^p]$, given as $D^p_{ij} = 3(d\bar{\varepsilon}^p/dt)\tau_{ij}/2\bar{\sigma}$. The numerical factors secure agreement between D^p_{11} and $d\bar{\varepsilon}^p/dt$ for uniaxial tension in the 1-direction. Also, the equation implies that $D^p_{11} + D^p_{22} + D^p_{33} = 0$ and that $d\bar{\varepsilon}^p/dt = \sqrt{(2/3)\mathrm{tr}([D^p][D^p])}$, which must be integrated over previous history to get $\bar{\varepsilon}^p$ as required for viscoplastic models in which $d\bar{\varepsilon}^p/dt$ is a function of $\bar{\sigma}$ and $\bar{\varepsilon}^p$. In the rate-independent version, $[D^p]$ is defined as zero whenever $\bar{\sigma}$ is less than the highest value that it has attained in the previous history or when the current value of $\bar{\sigma}$ is the highest value but $d\bar{\sigma}/dt < 0$. (In the elastic-plastic context, this means that "unloading" involves only elastic response.) For the ideally plastic solid, which is idealized to be able to flow without increase of stress when $\bar{\sigma}$ equals the yield strength level, $d\bar{\varepsilon}^p/dt$ is regarded as an undetermined but necessarily nonnegative parameter, which can be determined (sometimes not uniquely) only through the complete solution of a solid mechanics boundary-value problem.

The elastic-plastic material model is then formulated by writing $D_{ij} = D^e_{ij} + D^p_{ij}$, where D^p_{ij} is given in terms of stress and possibly stress rate as above and where the elastic deformation rates $[D^e]$ are related to stresses by the usual linear elastic expression $D^e_{ij} = (1+\nu)\dot{\sigma}^*_{ij}/E - \nu\delta_{ij}(\dot{\sigma}^*_{11} + \dot{\sigma}^*_{22} + \dot{\sigma}^*_{33})/E$. Here the stress rates are expressed as the Jaumann co-rotational rates $\dot{\sigma}^*_{ij} = \dot{\sigma}_{ij} + \sum_{k=1}^{3}(\sigma_{ik}\Omega_{kj} - \Omega_{ik}\sigma_{kj})$, where $\dot{\sigma}_{ij} = d\sigma_{ij}/dt$ is a derivative following the motion of a material point and where the spin Ω_{ij} is defined by $2\Omega_{ij} = \partial v_i/\partial x_j - \partial v_j/\partial x_i$. The co-rotational stress rates are those calculated by an observer who spins with the average angular velocity of a material element. The elastic part of the stress-strain relation should be consistent with the existence of a free energy f, as discussed above. This is not strictly satisfied by the form just given, but the differences between it and one which is consistent in that way involves additional terms that are on the order of $\bar{\sigma}/E^2$ times the $\dot{\sigma}^*_{kl}$ and are negligible in typical cases in which the theory is used, since $\bar{\sigma}/E$ is usually an extremely small fraction of unity, say, 10^{-4} to 10^{-2}. A small-strain version of the theory is in common use for purposes of elastic-plastic stress analysis. In these cases, $[D]$ is replaced with $\partial[\varepsilon(X, t)]/\partial t$, where $[\varepsilon]$ is the small-strain tensor, $\partial/\partial x$ with $\partial/\partial X$ in all equations, and $[\dot{\sigma}^*]$ with $\partial[\sigma(X, t)]/\partial t$. The last two steps cannot always be justified, even in cases of very small strain when, for example, in a rate-independent material, $d\bar{\sigma}/d\bar{\varepsilon}^p$ is not large compared to $\bar{\sigma}$ or when rates of rotation of material fibres can become much larger than rates of stretching, which is a concern for buckling problems even in purely elastic solids.

Small-strain theory

PROBLEMS INVOLVING ELASTIC RESPONSE

Equations of motion of linear elastic bodies. The final equations of the purely mechanical theory of linear elasticity (*i.e.*, when coupling with the temperature field is neglected, or when either isothermal or isentropic response is assumed) are obtained as follows. The stress-strain relations are used, and the strains are written in terms of displacement gradients. The final expressions for stress are inserted into the equations of motion, replacing $\partial/\partial x$ with $\partial/\partial X$ in those equations. In the case of an isotropic and homogenous solid, these reduce to

$$(\lambda + \mu)\nabla(\nabla \cdot \boldsymbol{u}) + \mu\nabla^2\boldsymbol{u} + \boldsymbol{f} = \frac{\rho\partial^2\boldsymbol{u}}{\partial t^2}, \qquad (116)$$

Navier equations

known as the Navier equations (here, $\nabla = \boldsymbol{e}_1\partial/\partial X_1 + \boldsymbol{e}_2\partial/\partial X_2 + \boldsymbol{e}_3\partial/\partial X_3$, and ∇^2 is the Laplacian operator defined by $\nabla \cdot \nabla$, or $\partial^2/\partial x_1^2 + \partial^2/\partial x_2^2 + \partial^2/\partial x_3^2$, and, as described earlier, λ and μ are the Lamé constants, $\boldsymbol{u}$ the displacement, $\boldsymbol{f}$ the body force, and ρ the density of the material). Such equations hold in the region V occupied by the solid; on the surface S one prescribes each component of $\boldsymbol{u}$, or each component of the stress vector $\boldsymbol{T}$ (expressed in terms of $[\partial u/\partial X]$), or sometimes mixtures of components or relations between them. For example, along a freely slipping planar interface with a rigid solid, the normal component of $\boldsymbol{u}$ and the two tangential components of $\boldsymbol{T}$ would be prescribed, all as zero.

Body wave solutions. By looking for body wave solutions in the form $\boldsymbol{u}(X, t) = \boldsymbol{p}f(\boldsymbol{n} \cdot X - ct)$, where unit vector $\boldsymbol{n}$ is the propagation direction, $\boldsymbol{p}$ is the polarization, or direction of particle motion, and c is the wave speed, one may show for the isotropic material that solutions exist for arbitrary functions f if either $c = c_d \equiv \sqrt{(\lambda + 2\mu)/\rho}$ and $\boldsymbol{p} = \boldsymbol{n}$, or $c = c_s \equiv \sqrt{\mu/\rho}$ and $\boldsymbol{p} \cdot \boldsymbol{n} = 0$. The first case, with particle displacements in the propagation direction, describes longitudinal, or dilatational, waves; and the latter case, which corresponds to two linearly independent displacement directions, both transverse to the propagation direction, describes transverse, or shear, waves.

Linear elastic beam. The case of a beam treated as a linear elastic line may also be considered. Let the line along the 1-axis (see Figure 43), have properties that are uniform along its length and have sufficient symmetry that bending it by applying a torque about the 3-direction causes the line to deform into an arc lying in the 1,2-plane. Make an imaginary cut through the line, and let the forces and torque acting at that section on the part lying in the direction of decreasing X_1 be denoted as a shear force V in the positive 2-direction, an axial force P in the positive 1-direction, and torque M, commonly called a bending moment, about the positive 3-direction. The linear and angular momentum principles then require that the actions at that section on the part of the line lying along the direction of increasing X_1 be of equal magnitude but opposite sign.

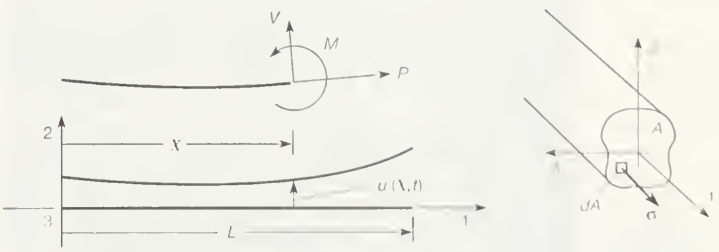

Figure 43: Transverse motion of an initially straight beam, shown at left as an elastic line and at right as a solid of finite section (see text).

Now let the line be loaded by transverse force F per unit length, directed in the 2-direction, and make assumptions on the smallness of deformation consistent with those of linear elasticity. Let ρA be the mass per unit length (so that A can be interpreted as the cross-sectional area of a homogeneous beam of density ρ) and let u be the transverse displacement in the 2-direction. Then, writing X for X_1, the linear and angular momentum principles require that $\partial V/\partial X + F = \rho A\, \partial^2 u/\partial t^2$ and $\partial M/\partial X + V = 0$, where rotary inertia has been neglected in the second equation, as is appropriate for disturbances which are of a wavelength that is long compared to cross-sectional dimensions. The curvature κ of the elastic line can be approximated by $\kappa = \partial^2 u/\partial X^2$ for the small deformation situation considered, and the equivalent of the stress-strain relation is to assume that κ is a function of M at each point along the line. The function can be derived by the analysis of stress and strain in pure bending and is $M = EI\kappa$, with the moment of inertia $I = \int_A (X_2)^2 dA$ for uniform elastic properties over all the cross section and with the 1-axis passing through the section centroid. Hence, the equation relating transverse load and displacement of a linear elastic beam is $-\partial^2(EI\partial^2 u/\partial X^2)/\partial X^2 + F = \rho A \partial^2 u/\partial t^2$, and this is to be solved subject to two boundary conditions at each end of the elastic line. Examples are $u = \partial u/\partial X = 0$ at a completely restrained ("built in") end, $u = M = 0$ at an end that is restrained against displacement but not rotation, and $V = M = 0$ at a completely unrestrained (free) end. The beam will be reconsidered later in an analysis of response with initial stress present.

Boundary conditions

The preceding derivation was presented in the spirit of the model of a beam as the elastic line of Euler. The same equations of motion may be obtained by the following five steps: (1) integrate the three-dimensional equations of motion over a section, writing $V = \int_A \sigma_{12} dA$; (2) integrate the product of X_2 and those equations over a section, writing $M = -\int_A X_2 \sigma_{11} dA$; (3) assume that planes initially perpendicular to fibres lying along the 1-axis remain perpendicular during deformation, so that $\varepsilon_{11} = \varepsilon_0(X, t) - X_2\kappa(X, t)$, where $X \equiv X_1$, $\varepsilon_0(X, t)$ is the strain of the fibre along the 1-axis, and $\kappa(X, t) = \partial^2 u/\partial X^2$, where $u(X, t)$ is u_2 for the fibre initially along the 1-axis; (4) assume that the stress σ_{11} relates to strain as if each point were under uniaxial tension, so that $\sigma_{11} = E\varepsilon_{11}$; and (5) neglect terms of order h^2/L^2 compared to unity, where h is a typical cross-section dimension and L is a scale length for variations along the direction of the 1-axis. In step (1) the average of u_2 over area A enters but may be interpreted as the displacement u of step (3) to the order retained in (5). The kinematic assumption (3) together with (5), if implemented under conditions such that there are no loadings to generate a net axial force P, requires that $\varepsilon_0(X, t) = 0$ and that $\kappa(X, t) = M(X, t)/EI$ when the 1-axis has been chosen to pass through the centroid of the cross section. Hence, according to these approximations, $\sigma_{11} = -X_2 M(X, t)/I = -X_2 E\partial^2 u(X, t)/\partial X^2$. The expression for σ_{11} is exact for static equilibrium under pure bending, since assumptions (3) and (4) are exact and (5) is then irrelevant. This motivates the use of assumptions (3) and (4) in a situation that does not correspond to pure bending.

Sometimes it is necessary to deal with solids that are already under stress in the reference configuration that is chosen for measuring strain. As a simple example, suppose that the beam just discussed is under an initial uniform tensile stress $\sigma_{11} = \sigma^0$—that is, the axial force $P = \sigma^0 A$. If σ^0 is negative and of significant magnitude, one generally refers to the beam as a column; if it is large and positive, the beam might respond more like a taut string. The initial stress σ^0 contributes a term to the equations of small transverse motion, which now becomes $-\partial^2(EI\partial^2 u/\partial X^2)/\partial X^2 + \sigma^0 A \partial^2 u/\partial X^2 + F = \rho A \partial^2 u/\partial t^2$.

Initial stress

Free vibrations. Suppose that the beam is of length L, is of uniform properties, and is hinge-supported at its ends at $X = 0$ and $X = L$ so that $u = M = 0$ there. Then free transverse motions of the beam, solving the above equation with $F = 0$, are described by any linear combination of the real part of solutions that have the form $u = C_n \exp(i\omega_n t)\sin(n\pi X/L)$, where n is any positive integer, C_n is an arbitrary complex constant, and where

$$\rho A \omega_n^2 = \left(\frac{n\pi}{L}\right)^4 EI\left[1 + \left(\frac{\sigma^0}{E}\right)\left(\frac{AL^2}{n^2\pi^2 I}\right)\right] \qquad (117)$$

defines the angular vibration frequency ω_n associated with the nth mode, in units of radians per unit time. The number of vibration cycles per unit time is $\omega_n/2\pi$. Equation (117) is arranged so that the term in the brackets shows the correction, from unity, of what would be the expression giving the frequencies of free vibration for a beam when there is no σ^0. The correction from unity can be quite significant, even though σ^0/E is always much smaller than unity (for interesting cases, 10^{-6} to, say, 10^{-3} would be a representative range; few materials in bulk form would remain elastic or resist fracture at higher σ^0/E, although good piano wire could reach about 10^{-2}). The correction term's significance results because σ^0/E is multiplied by a term that can become enormous for a beam that is long compared to its thickness; for a square section of side length h, that term (at its largest, when $n = 1$) is $AL^2/\pi^2 I \approx 1.2L^2/h^2$, which can combine with a small σ^0/E to produce a correction term within the brackets that is quite non-negligible compared to unity. When $\sigma^0 > 0$ and L is large enough to make the bracketed expression much larger than unity, the EI term cancels out and the beam simply responds like a stretched string (here, string denotes an object that is unable to support a bending moment). When the vibration mode number n is large enough, however, the stringlike effects become negligible and beamlike response takes over; at sufficiently high n that L/n is reduced to the same order as h, the simple beam theory becomes inaccurate and should be replaced by three-dimensional elasticity or, at least, an improved beam theory that takes into account rotary inertia and shear deformability. (While the option of using three-dimensional elasticity for such a problem posed an insurmountable obstacle over most of the history of the subject, by 1990 the availability of computing power and easily used software reduced it to a routine problem that could be studied by an undergraduate engineer or physicist using the finite-element method or some other computational mechanics technique.)

Buckling. An important case of compressive loading is that in which $\sigma^0 < 0$, which can lead to buckling. Indeed, if $\sigma^0 A < -\pi^2 EI/L^2$, then the ω_n^2 is negative, at least for $n = 1$, which means that the corresponding ω_n is of the form $\pm ib$, where b is a positive real number, so that the $\exp(i\omega_n t)$ term has a time dependence of a type that no longer involves oscillation but, rather, exponential growth, $\exp(bt)$. The critical compressive force, $\pi^2 EI/L^2$, that causes this type of behaviour is called the Euler buckling load; different numerical factors are obtained for different end conditions. The acceleration associated with the $n = 1$ mode becomes small in the vicinity of the critical load and vanishes at that load. Thus solutions are possible, at the buckling load, for which the column takes a deformed shape without acceleration; for that reason, an approach to buckling problems that is equivalent for what, in dynamic terminology, are called conservative systems is to seek the first load at which an alternate equilibrium solution $u = u(X)$, other than $u = 0$, may exist.

Instability by divergence—that is, with growth of displacement in the form $\exp(bt)$—is representative of conservative systems. Columns under nonconservative loadings by, for example, a follower force, which has the property that its line of action rotates so as to be always tangent to the beam centerline at its place of application, can exhibit a flutter instability in which the dynamic response is proportional to the real or imaginary part of a term such as $\exp(iat)\exp(bt)$—*i.e.*, an oscillation with exponentially growing amplitude. Such instabilities also arise in the coupling between fluid flow and elastic structural response, as in the subfield called aeroelasticity. The prototype is the flutter of an airplane wing—that is, a torsional oscillation of the wing, of growing amplitude, which is driven by the coupling between rotation of the wing and the development of aerodynamic forces related to the angle of attack; the coupling feeds more energy into the structure with each cycle.

Instability

Of course, instability models that are based on linearized theories and predicting exponential growth in time actu-

ally reveal no more than that the system is deforming out of the range for which the mathematical model applies. Proper nonlinear theories that take account of the finiteness of rotation, and sometimes the large and possibly nonelastic strain of material fibres, are necessary to really understand the phenomena. An important subclass of such nonlinear analyses for conservative systems involves the static post-buckling response of a perfect structure, such as a perfectly straight column or perfectly spherical shell. That post-buckling analysis allows one to determine if increasing force is required for very large displacement to develop during the buckle or whether the buckling is of a more highly unstable type for which the load must diminish with buckling amplitude in order to still satisfy the equilibrium equations. The latter type of behaviour describes a structure whose maximum load (that is, the largest load it can support without collapsing) shows strong sensitivity to very small imperfections of material or geometry, as is the case with many shell structures.

(J.R.R.)

FLUID MECHANICS

Fluid mechanics is concerned with the response of fluids to forces exerted upon them. It is a branch of classical physics with applications of great importance in hydraulic and aeronautical engineering, chemical engineering, meteorology, and zoology.

Hydrostatics and hydrodynamics

The most familiar fluid is of course water, and an encyclopaedia of the 19th century probably would have dealt with the subject under the separate headings of hydrostatics, the science of water at rest, and hydrodynamics, the science of water in motion. Archimedes founded hydrostatics in about 250 BC when, according to legend, he leapt out of his bath and ran naked through the streets of Syracuse crying "Eureka!"; it has undergone rather little development since. The foundations of hydrodynamics, on the other hand, were not laid until the 18th century when mathematicians such as Leonhard Euler and Daniel Bernoulli began to explore the consequences, for a virtually continuous medium like water, of the dynamic principles that Newton had enunciated for systems composed of discrete particles. Their work was continued in the 19th century by several mathematicians and physicists of the first rank, notably G.G. Stokes and William Thomson. By the end of the century explanations had been found for a host of intriguing phenomena having to do with the flow of water through tubes and orifices, the waves that ships moving through water leave behind them, raindrops on windowpanes, and the like. There was still no proper understanding, however, of problems as fundamental as that of water flowing past a fixed obstacle and exerting a drag force upon it; the theory of potential flow, which worked so well in other contexts, yielded results that at relatively high flow rates were grossly at variance with experiment. This problem was not properly understood until 1904, when the German physicist Ludwig Prandtl introduced the concept of the boundary layer (see below *Hydrodynamics: Boundary layers and separation*). Prandtl's career continued into the period in which the first manned aircraft were developed. Since that time, the flow of air has been of as much interest to physicists and engineers as the flow of water, and hydrodynamics has, as a consequence, become fluid dynamics. The term fluid mechanics, as used here, embraces both fluid dynamics and the subject still generally referred to as hydrostatics.

One other representative of the 20th century who deserves mention here besides Prandtl is Geoffrey Taylor of England. Taylor remained a classical physicist while most of his contemporaries were turning their attention to the problems of atomic structure and quantum mechanics, and he made several unexpected and important discoveries in the field of fluid mechanics. The richness of fluid mechanics is due in large part to a term in the basic equation of the motion of fluids which is nonlinear—*i.e.*, one that involves the fluid velocity twice over. It is characteristic of systems described by nonlinear equations that under certain conditions they become unstable and begin behaving in ways that seem at first sight to be totally chaotic. In the case of fluids, chaotic behaviour is very common and is called turbulence. Mathematicians have now begun to recognize patterns in chaos that can be analyzed fruitfully, and this development suggests that fluid mechanics will remain a field of active research well into the 21st century. (For a discussion of the concept of chaos, see PHYSICAL SCIENCE, PRINCIPLES OF.)

Fluid mechanics is a subject with almost endless ramifications, and the account that follows is necessarily incomplete. Some knowledge of the basic properties of fluids will be needed; a survey of the most relevant properties is given in the next section. For further details, see THERMODYNAMICS, PRINCIPLES OF; and MATTER: *Liquid state*.

Basic properties of fluids

Fluids are not strictly continuous media in the way that all the successors of Euler and Bernoulli have assumed, for they are composed of discrete molecules. The molecules, however, are so small and, except in gases at very low pressures, the number of molecules per millilitre is so enormous that they need not be viewed as individual entities. There are a few liquids, known as liquid crystals, in which the molecules are packed together in such a way as to make the properties of the medium locally anisotropic, but the vast majority of fluids (including air and water) are isotropic. In fluid mechanics, the state of an isotropic fluid may be completely described by defining its mean mass per unit volume, or density (ρ), its temperature (T), and its velocity (v) at every point in space, and just what the connection is between these macroscopic properties and the positions and velocities of individual molecules is of no direct relevance.

A word perhaps is needed about the difference between gases and liquids, though the difference is easier to perceive than to describe. In gases the molecules are sufficiently far apart to move almost independently of one another, and gases tend to expand to fill any volume available to them. In liquids the molecules are more or less in contact, and the short-range attractive forces between them make them cohere; the molecules are moving too fast to settle down into the ordered arrays that are characteristic of solids, but not so fast that they can fly apart. Thus, samples of liquid can exist as drops or as jets with free surfaces, or they can sit in beakers constrained only by gravity, in a way that samples of gas cannot. Such samples may evaporate in time, as molecules one by one pick up enough speed to escape across the free surface and are not replaced. The lifetime of liquid drops and jets, however, is normally long enough for evaporation to be ignored.

There are two sorts of stress that may exist in any solid or fluid medium, and the difference between them may be illustrated by reference to a brick held between two hands. If the holder moves his hands toward each other, he exerts pressure on the brick; if he moves one hand toward his body and the other away from it, then he exerts what is called a shear stress. A solid substance such as a brick can withstand stresses of both types, but fluids, by definition, yield to shear stresses no matter how small these stresses may be. They do so at a rate determined by the fluid's viscosity. This property, about which more will be said later, is a measure of the friction that arises when adjacent layers of fluid slip over one another. It follows that the shear stresses are everywhere zero in a fluid at rest and in equilibrium, and from this it follows that the pressure (that is, force per unit area) acting perpendicular to all planes in the fluid is the same irrespective of their orientation (Pascal's law). For an isotropic fluid in equilibrium there is only one value of the local pressure (p) consistent with the stated values for ρ and T. These three quantities are linked together by what is called the equation of state for the fluid.

Equation of state

For gases at low pressures the equation of state is simple and well known. It is

$$p = \left(\frac{RT}{M}\right)\rho, \tag{118}$$

where R is the universal gas constant (8.3 joules per degree Celsius per mole) and M is the molar mass, or an average molar mass if the gas is a mixture; for air, the appropriate average is about 29×10^{-3} kilogram per mole. For other fluids knowledge of the equation of state is often incomplete. Except under very extreme conditions, however, all one needs to know is how the density changes when the pressure is changed by a small amount, and this is described by the compressibility of the fluid—either the isothermal compressibility, β_T, or the adiabatic compressibility, β_S, according to circumstance. When an element of fluid is compressed, the work done on it tends to heat it up. If the heat has time to drain away to the surroundings and the temperature of the fluid remains essentially unchanged throughout, then β_T is the relevant quantity. If virtually none of the heat escapes, as is more commonly the case in flow problems because the thermal conductivity of most fluids is poor, then the flow is said to be adiabatic, and β_S is needed instead. (The S refers to entropy, which remains constant in an adiabatic process provided that it takes place slowly enough to be treated as "reversible" in the thermodynamic sense.) For gases that obey equation (118), it is evident that p and ρ are proportional to one another in an isothermal process, and

$$\beta_T = \rho^{-1}\left(\frac{\partial \rho}{\partial p}\right)_T = p^{-1}. \tag{119}$$

In reversible adiabatic processes for such gases, however, the temperature rises on compression at a rate such that

$$T \propto \rho^{(\gamma-1)}, \quad p \propto \rho^{\gamma}, \tag{120}$$

and

$$\beta_S = \rho^{-1}\left(\frac{\partial \rho}{\partial p}\right)_S = (\gamma p)^{-1} = \frac{\beta_T}{\gamma}, \tag{121}$$

where γ is about 1.4 for air and takes similar values for other common gases. For liquids the ratio between the isothermal and adiabatic compressibilities is much closer to unity. For liquids, however, both compressibilities are normally much less than p^{-1}, and the simplifying assumption that they are zero is often justified.

Molar specific heat

The factor γ is not only the ratio between two compressibilities; it is also the ratio between two principal specific heats. The molar specific heat is the amount of heat required to raise the temperature of one mole through one degree. This is greater if the substance is allowed to expand as it is heated, and therefore to do work, than if its volume is fixed. The principal molar specific heats, C_P and C_V, refer to heating at constant pressure and constant volume, respectively, and

$$\gamma = \frac{C_P}{C_V}. \tag{122}$$

For air, C_P is about 3.5 R.

Solids can be stretched without breaking, and liquids, though not gases, can withstand stretching, too. Thus, if the pressure is steadily reduced in a specimen of very pure water, bubbles will ultimately appear, but they may not do so until the pressure is negative and well below -10^7 newton per square metre; this is 100 times greater in magnitude than the (positive) pressure exerted by the Earth's atmosphere. Water owes its high ideal strength to the fact that rupture involves breaking links of attraction between molecules on either side of the plane on which rupture occurs; work must be done to break these links. However, its strength is drastically reduced by anything that provides a nucleus at which the process known as cavitation (formation of vapour- or gas-filled cavities) can begin, and a liquid containing suspended dust particles or dissolved gases is liable to cavitate quite easily.

Work also must be done if a free liquid drop of spherical shape is to be drawn out into a long thin cylinder or deformed in any other way that increases its surface area. Here again work is needed to break intermolecular links.

Surface tension

The surface of a liquid behaves, in fact, as if it were an elastic membrane under tension, except that the tension exerted by an elastic membrane increases when the membrane is stretched in a way that the tension exerted by a liquid surface does not. Surface tension is what causes liquids to rise up capillary tubes, what supports hanging liquid drops, what limits the formation of ripples on the surface of liquids, and so on.

Hydrostatics

It is common knowledge that the pressure of the atmosphere (about 10^5 newtons per square metre) is due to the weight of air above the Earth's surface, that this pressure falls as one climbs upward, and, correspondingly, that pressure increases as one dives deeper into a lake (or comparable body of water). Mathematically, the rate at which the pressure in a stationary fluid varies with height z in a vertical gravitational field of strength g is given by

$$\frac{dp}{dz} = -\rho g. \tag{123}$$

If ρ and g are both independent of z, as is more or less the case in lakes, then

$$p(z) = p(0) - \rho g z. \tag{124}$$

This means that, since ρ is about 10^3 kilograms per cubic metre for water and g is about 10 metres per second squared, the pressure is already twice the atmospheric value at a depth of 10 metres. Applied to the atmosphere, equation (124) would imply that the pressure falls to zero at a height of about 10 kilometres. In the atmosphere, however, the variation of ρ with z is far from negligible and (124) is unreliable as a consequence; a better approximation is given below in the section *Hydrodynamics: Compressible flow in gases*.

Differential manometers

Instruments for comparing pressures are called differential manometers, and the simplest such instrument is a U-tube containing liquid, as shown in Figure 44A. The two pressures of interest, p_1 and p_2, are transmitted to the two ends of the liquid column through an inert gas—the density of which is negligible by comparison with the liquid density, ρ—and the difference of height, h, of the two menisci is measured. It is a consequence of (124) that

$$p_1 - p_2 = \rho g h. \tag{125}$$

A barometer for measuring the pressure of the atmosphere in absolute terms is simply a manometer in which p_2 is made zero, or as close to zero as is feasible. The barometer invented in the 17th century by the Italian physicist and mathematician Evangelista Torricelli, and still in use today, is a U-tube that is sealed at one end (see Figure 44B). It may be filled with liquid, with the sealed end downward, and then inverted. On inversion, a negative pressure may momentarily develop at the top of the liquid column if the column is long enough; however, cavitation normally occurs there and the column falls away from the sealed end of the tube, as shown in the figure. Between the two exists what Torricelli thought of as a vacuum, though it may be very far from that condition if the barometer has been filled without scrupulous precautions to ensure that all dissolved or adsorbed gases, which would otherwise collect in this space, have first been removed. Even if no contaminating gas is present, the Torricellian vacuum always contains the vapour of the liquid, and this exerts a pressure which may be small but is never quite zero. The liquid conventionally used in a Torricelli barometer is of course mercury, which has a low vapour pressure and a high density. The high density means that h is only about 760 millimetres; if water were used, it would have to be about 10 metres instead.

Figure 44C illustrates the principle of the siphon. The top container is open to the atmosphere, and the pressure in it, p_2, is therefore atmospheric. To balance this and the weight of the liquid column in between, the pressure p_1 in the bottom container ought to be greater by $\rho g h$. If the bottom container is also open to the atmosphere, then equilibrium is clearly impossible; the weight of the liquid column prevails and causes the liquid to flow downward.

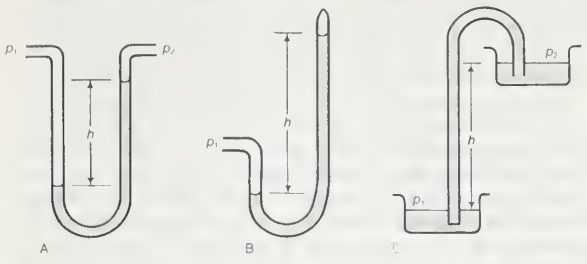

Figure 44: Schematic representations of (A) a differential manometer, (B) a Torricellian barometer, and (C) a siphon.

The siphon operates only as long as the column is continuous; it fails if a bubble of gas collects in the tube or if cavitation occurs. Cavitation therefore limits the level differences over which siphons can be used, and it also limits (to about 10 metres) the depth of wells from which water can be pumped using suction alone.

Consider now a cube of side d totally immersed in liquid with its top and bottom faces horizontal. The pressure on the bottom face will be higher than on the top by $\rho g d$, and, since pressure is force per unit area and the area of a cube face is d^2, the resultant upthrust on the cube is $\rho g d^3$. This is a simple example of the so-called Archimedes' principle, which states that the upthrust experienced by a submerged or floating body is always equal to the weight of the liquid that the body displaces. As Archimedes must have realized, there is no need to prove this by detailed examination of the pressure difference between top and bottom. It is obviously true, whatever the body's shape. It is obvious because, if the solid body could somehow be removed and if the cavity thereby created could somehow be filled with more fluid instead, the whole system would still be in equilibrium. The extra fluid would, however, then be experiencing the upthrust previously experienced by the solid body, and it would not be in equilibrium unless this were just sufficient to balance its weight.

Archimedes' principle

Archimedes' problem was to discover, by what would nowadays be called a nondestructive test, whether the crown of King Hieron II was made of pure gold or of gold diluted with silver. He understood that the pure metal and the alloy would differ in density and that he could determine the density of the crown by weighing it to find its mass and making a separate measurement of its volume. Perhaps the inspiration that struck him (in his bath) was that one can find the volume of any object by submerging it in liquid in something like a measuring cylinder (*i.e.*, in a container with vertical sides that have been suitably graduated) and measuring the displacement of the liquid surface. If so, he no doubt realized soon afterward that a more elegant and more accurate method for determining density can be based on the principle that bears his name. This method involves weighing the object twice, first, when it is suspended in a vacuum (suspension in air will normally suffice) and, second, when it is totally submerged in a liquid of density ρ. If the density of the object is ρ', the ratio between the two weights must be

$$\frac{W_2}{W_1} = \frac{(\rho' - \rho)}{\rho'}. \qquad (126)$$

If ρ' is less than ρ, then W_2, according to equation (126), is negative. What that means is that the object does not submerge of its own accord; it has to be pushed downward to make it do so. If an object with a mean density less than that of water is placed in a lake and not subjected to any downward force other than its own weight, it naturally floats on the surface, and Archimedes' principle shows that in equilibrium the volume of water which it displaces is a fraction ρ'/ρ of its own volume. A hydrometer is an object graduated in such a way that this fraction may be measured. By floating a hydrometer first in water of density ρ_0 and then in some other liquid of density ρ_1 and comparing the readings, one may determine the ratio ρ_1/ρ_0—*i.e.*, the specific gravity of the other liquid.

In what orientation an object floats is a matter of grave concern to those who design boats and those who travel in them. A simple example will suffice to illustrate the factors that determine orientation. Figure 45 shows three of the many possible orientations that a uniform square prism might adopt when floating, with half its volume submerged in a liquid for which $\rho = 2\rho'$; they are separated by rotations of 22.5°. In each of these diagrams, C is the centre of mass of the prism, and B, a point known as the centre of buoyancy, is the centre of mass of the displaced water. The distributed forces acting on the prism are equivalent to its weight acting downward through C and to the equal weight of the displaced water acting upward through B. In general, therefore, the prism experiences a torque. In Figure 45B the torque is counterclockwise, and so it turns the prism away from 45A and toward 45C. In 45C the torque vanishes because B is now vertically below C, and this is the orientation that corresponds to stable equilibrium. The torque also vanishes in 45A, and the prism can in principle remain indefinitely in that orientation as well; the equilibrium in this case, however, is unstable, and the slightest disturbance will cause the prism to topple one way or the other. In fact, the potential energy of the system, which increases in a linear fashion with the difference in height between C and B, is at its smallest in orientation 45C and at its largest in orientation 45A. To improve the stability of a floating object one should, if possible, lower C relative to B. In the case of a boat, this may be done by redistributing the load inside.

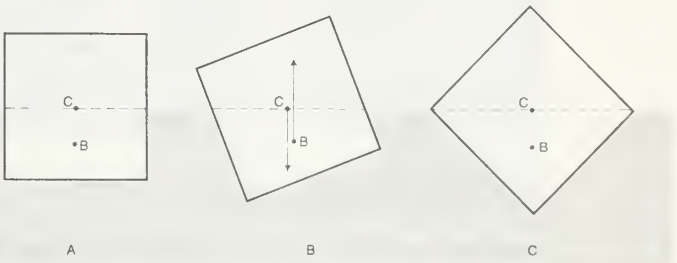

Figure 45: Three possible orientations of a uniform square prism floating in liquid of twice its density. The stable orientation is (C) (see text).

Of the many hydrostatic phenomena in which the surface tension of liquids plays a role, the most significant is probably capillarity. Consider what happens when a tube of narrow bore, often called a capillary tube, is dipped into a liquid. If the liquid "wets" the tube (with zero contact angle), the liquid surface inside the tube forms a concave meniscus, which is a virtually spherical surface having the same radius, r, as the inside of the tube. The tube experiences a downward force of magnitude $2\pi r\sigma$, where σ is the surface tension of the liquid, and the liquid experiences a reaction of equal magnitude that lifts the meniscus through a height h such that

Capillarity

$$2\pi r\sigma = \pi r^2 h\rho g \qquad (127)$$

—*i.e.*, until the upward force for which surface tension is responsible is balanced by the weight of the column of liquid that has been lifted. If the liquid does not wet the tube, the meniscus is convex and depressed through the same distance h (see Figure 46). A simple method for determining surface tension involves the measurement of h in one or the other of these situations and the use of equation (127) thereafter.

It follows from equations (124) and (127) that the pressure at a point P just below the meniscus differs from the pressure at Q by an amount

$$\rho g h = \frac{2\sigma}{r}; \qquad (128)$$

it is less than the pressure at Q in the case to which Figure 46A refers and greater than the pressure at Q in the other case. Since the pressure at Q is just the atmospheric pressure, it is equal to the pressure at a point immediately above the meniscus. Hence, in both instances there is a pressure difference of $2\sigma/r$ between the two sides of the curved meniscus, and in both the higher pressure is on the inner side of the curve. Such a pressure difference is a requirement of equilibrium wherever a liquid surface is curved. If the surface is curved but not spherical, the pressure difference is

$$\sigma(r_1^{-1} + r_2^{-1}), \qquad (129)$$

where r_1 and r_2 are the two principal radii of curvature. If it is cylindrical, one of these radii is infinite, and, if it is curved in opposite directions, then for the purposes of (129) they should be treated as being of opposite sign.

The diagrams in Figure 46 were drawn to represent cross sections through cylindrical tubes, but they might equally well represent two vertical parallel plates that are partly submerged in the liquid a small distance apart. Consideration of how the pressure varies with height shows that over the range of height h the plates experience a greater pressure on their outer surfaces than on their inner surfaces; this is true whether the liquid wets both plates or not. It is a matter of observation that small objects floating near one another on the surface of a liquid tend to move toward one another, and it is the pressure difference just referred to that makes them behave in this way.

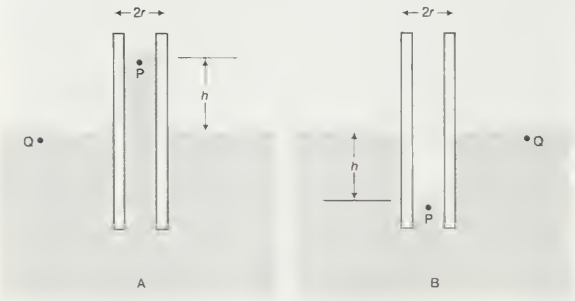

Figure 46: *Capillarity.*
(A) The liquid wets the tube and rises up in it. (B) The liquid does not wet the tube and is depressed.

One other problem having to do with surface tension will be considered here. The diagrams in Figure 47 show stages in the growth of a liquid drop on the end of a tube which the liquid is supposed to wet. In passing from stage A to stage B, by which time the drop is roughly hemispheric in shape, the radius of curvature of the drop diminishes; and it follows from (128) that, to bring about this growth, one must slowly increase the pressure of the liquid inside the tube. If the pressure could be held steady at the value corresponding to B, the drop would then become unstable, because any further growth (*e.g.*, to the more or less spherical shape indicated in Figure 47C) would involve an increase in radius of curvature. The applied pressure would then exceed that required to hold the drop in equilibrium, and the drop would necessarily grow bigger still. In practice, however, it is easier to control the rate of flow of water through the tube, and hence the rate of growth of the drop, than it is to control the pressure. If the rate of flow is very small, drops will form the nonspherical shapes suggested by Figure 47D before they detach themselves and fall. It is not an easy matter to analyze the shape of a drop on the point of detachment, and there is no simple formula for the volume of the drop after it is detached.

Figure 47: Stages in the formation of a liquid drop (see text).

Hydrodynamics

BERNOULLI'S LAW

Fluids in steady motion

Up to now the focus has been fluids at rest. This section deals with fluids that are in motion in a steady fashion such that the fluid velocity at each given point in space is not changing with time. Any flow pattern that is steady in this sense may be seen in terms of a set of streamlines, the trajectories of imaginary particles suspended in the fluid and carried along with it. In steady flow, the fluid is in motion but the streamlines are fixed. Where the streamlines crowd together, the fluid velocity is relatively high; where they open out, the fluid becomes relatively stagnant.

When Euler and Bernoulli were laying the foundations of hydrodynamics, they treated the fluid as an idealized inviscid substance in which, as in a fluid at rest in equilibrium, the shear stresses associated with viscosity are zero and the pressure p is isotropic. They arrived at a simple law relating the variation of p along a streamline to the variation of v (the principle is credited to Bernoulli, but Euler seems to have arrived at it first), which serves to explain many of the phenomena that real fluids in steady motion display. To the inevitable question of when and why it is justifiable to neglect viscosity, there is no single answer. Some answers will be provided later in this article, but other matters will be taken up first.

Consider a small element of fluid of mass m, which—apart from the force on it due to gravity—is acted on only by a pressure p. The latter is isotropic and does not vary with time but may vary from point to point in space. It is a well-known consequence of Newton's laws of motion that, when a particle of mass m moves under the influence of its weight mg and an additional force $\boldsymbol{F}$ from a point P where its speed is v_P and its height is z_P to a point Q where its speed is v_Q and its height is z_Q, the work done by the additional force is equal to the increase in kinetic and potential energy of the particle—*i.e.*, that

$$\int_P^Q \boldsymbol{F}\cdot d\boldsymbol{s} = \left(\frac{1}{2}\right)m(v_Q^2 - v_P^2) + mg(z_Q - z_P). \qquad (130)$$

In the case of the fluid element under consideration, $\boldsymbol{F}$ may be related in a simple fashion to the gradient of the pressure, and one finds

$$\int_P^Q \boldsymbol{F}\cdot d\boldsymbol{s} = -m\int_P^Q \rho^{-1}dp. \qquad (131)$$

If the variations of fluid density along the streamline from P to Q are negligibly small, the factor ρ^{-1} may be taken outside the integral on the right-hand side of (131), which thereupon reduces to $\rho^{-1}(p_Q - p_P)$. Then (130) and (131) can be combined to obtain

$$\frac{p_P}{\rho} + \frac{v_P^2}{2} + gz_P = \frac{p_Q}{\rho} + \frac{v_Q^2}{2} + gz_Q. \qquad (132)$$

Since this applies for any two points that can be visited by a single element of fluid, one can immediately deduce Bernoulli's (or Euler's) important result that along each streamline in the steady flow of an inviscid fluid the quantity

$$\left(\frac{p}{\rho} + \frac{v^2}{2} + gz\right) \qquad (133)$$

is constant.

Under what circumstances are variations in the density negligibly small? When they are very small compared with the density itself—*i.e.*, when

$$\left(\frac{\Delta\rho}{\rho}\right) = \beta_S\Delta p = (\beta_S\rho)\Delta\left(\frac{v^2}{2} + gz\right) = \frac{\Delta\left(\frac{v^2}{2} + gz\right)}{V_S^2} \ll 1, \qquad (134)$$

where the symbol Δ is used to represent the extent of the change along a streamline of the quantity that follows it, and where V_S is the speed of sound (see below *Compressible flow in gases*). This condition is satisfied for all the flow problems having to do with water that are discussed below. If the fluid is air, it is adequately satisfied provided that the largest excursion in z is on the order of metres rather than kilometres and provided that the fluid velocity is everywhere less than about 100 metres per second.

Bernoulli's law indicates that, if an inviscid fluid is flowing along a pipe of varying cross section, then the pressure is relatively low at constrictions where the velocity is high and relatively high where the pipe opens out and the fluid stagnates. Many people find this situation paradoxical when they first encounter it. Surely, they say, a constriction should increase the local pressure rather than diminish it? The paradox evaporates as one learns to think

of the pressure changes along the pipe as cause and the velocity changes as effect, instead of the other way around; it is only because the pressure falls at a constriction that the pressure gradient upstream of the constriction has the right sign to make the fluid accelerate.

Paradoxical or not, predictions based on Bernoulli's law are well-verified by experiment. Try holding two sheets of paper so that they hang vertically two centimetres or so apart and blow downward so that there is a current of air between them. The sheets will be drawn together by the reduction in pressure associated with this current. Ships are drawn together for much the same reason if they are moving through the water in the same direction at the same speed with a small distance between them. In this case, the current results from the displacement of water by each ship's bow, which has to flow backward to fill the space created as the stern moves forward, and the current between the ships, to which they both contribute, is stronger than the current moving past their outer sides. As another simple experiment, listen to the hissing sound made by a tap that is almost, but not quite, turned off. What happens in this case is that the flow is so constricted and the velocity within the constriction so high that the pressure in the constriction is actually negative. Assisted by the dissolved gases that are normally present, the water cavitates as it passes through, and the noise that is heard is the sound of tiny bubbles collapsing as the water slows down and the pressure rises again on the other side.

Venturi and pitot tubes

Two practical devices that are used by hydraulic engineers to monitor the flow of liquids though pipes are based on Bernoulli's law. One is the venturi tube, a short length with a constriction in it of standard shape (see Figure 48A), which may be inserted into the pipe proper. If the velocity at point P, where the tube has a cross-sectional area A_P, is v_P and the velocity in the constriction, where the area is A_Q, is v_Q, the continuity condition—the condition that the mass flowing through the pipe per unit time has to be the same at all points along its length—suggests that $\rho_P A_P v_P = \rho_Q A_Q v_Q$, or that $A_P v_P = A_Q v_Q$ if the difference between ρ_P and ρ_Q is negligible. Then Bernoulli's law indicates

$$\rho gh = (p_P - p_Q) = \left(\frac{1}{2}\right)\rho v_P^2\left[\left(\frac{A_P}{A_Q}\right)^2 - 1\right]. \qquad (135)$$

Thus one should be able to find v_P, and hence the quantity Q $(= A_P v_P)$ that engineers refer to as the rate of discharge, by measuring the difference of level h of the fluid in the two side tubes shown in the diagram. At low velocities the pressure difference $(p_P - p_Q)$ is greatly affected by viscosity (see below *Viscosity*), and equation (135) is unreliable in consequence. The venturi tube is normally used, however, when the velocity is large enough for the flow to be turbulent (see below *Turbulence*). In such a circumstance, equation (135) predicts values for Q that agree with values measured by more direct means to within a few parts percent, even though the flow pattern is not really steady at all.

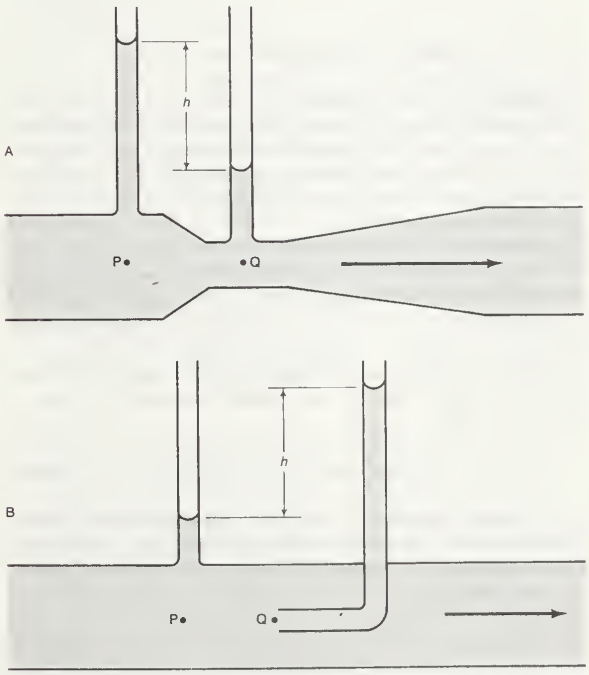

Figure 48: Schematic representation of (A) a venturi tube and of (B) a pitot tube.

The other device is the pitot tube, which is illustrated in Figure 48B. The fluid streamlines divide as they approach the blunt end of this tube, and at the point marked Q in the diagram there is complete stagnation, since the fluid at this point is moving neither up nor down nor to the right. It follows immediately from Bernoulli's law that

$$\rho gh = (p_Q - p_P) = \left(\frac{1}{2}\right)\rho v_P^2. \qquad (136)$$

As with the venturi tube, one should therefore be able to find v_P from the level difference h.

One other simple result deserves mention here. It concerns a jet of fluid emerging through a hole in the wall of a vessel filled with liquid under pressure. Observation of jets shows that after emerging they narrow slightly before settling down to a more or less uniform cross section known as the vena contracta. They do so because the streamlines are converging on the hole inside the vessel and are obliged to continue converging for a short while outside. It was Torricelli who first suggested that, if the pressure excess inside the vessel is generated by a head of liquid h, then the velocity v at the vena contracta is the velocity that a free particle would reach on falling through a height h—*i.e.*, that

$$v = \sqrt{(2gh)}. \qquad (137)$$

This result is an immediate consequence, for an inviscid fluid, of the principle of energy conservation that Bernoulli's law enshrines.

In the following section, Bernoulli's law is used in an indirect way to establish a formula for the speed at which disturbances travel over the surface of shallow water. The explanation of several interesting phenomena having to do with water waves is buried in this formula. Analogous phenomena dealing with sound waves in gases are discussed below in *Compressible flow in gases*, where an alternative form of Bernoulli's law is introduced. This form of the law is restricted to gases in steady flow but is not restricted to flow velocities that are much less than the speed of sound. The complication that viscosity represents is again ignored throughout these two sections.

WAVES ON SHALLOW WATER

Imagine a layer of water with a flat base that has a small step on its surface, dividing a region in which the depth of the water is uniformly equal to D from a region in which it is uniformly equal to $D(1+\varepsilon)$, with $\varepsilon << 1$. Let the water in the shallower region flow toward the step with some uniform speed V, as Figure 49A suggests, and let this speed be just sufficient to hold the step in the same position so that the flow pattern is a steady one. The continuity condition (*i.e.*, the condition that as much water flows out to the left per unit time as flows in from the right) indicates that in the deeper region the speed of the water is $V(1+\varepsilon)^{-1}$. Hence by applying Bernoulli's law to the points marked P and Q in the diagram, which lie on the same streamline and at both of which the pressure is atmospheric, one may deduce that

$$g\varepsilon D = \left(\frac{1}{2}\right)V^2[1 - (1+\varepsilon)^{-2}] \approx \varepsilon V^2$$

—*i.e.*, that

$$V = \sqrt{(gD)}. \qquad (138)$$

This result shows that, if the water in the shallower region is in fact stationary (see Figure 49B), the step advances over it with the speed V that equation (138) describes, and it reveals incidentally that behind the step the deeper water follows up with speed $V[1-(1+\varepsilon)^{-1}] \approx \varepsilon V$. The argument may readily be extended to disturbances of the surface that are undulatory rather than steplike. Provided that the distance between successive crests—a distance known as the wavelength and denoted by λ—is much

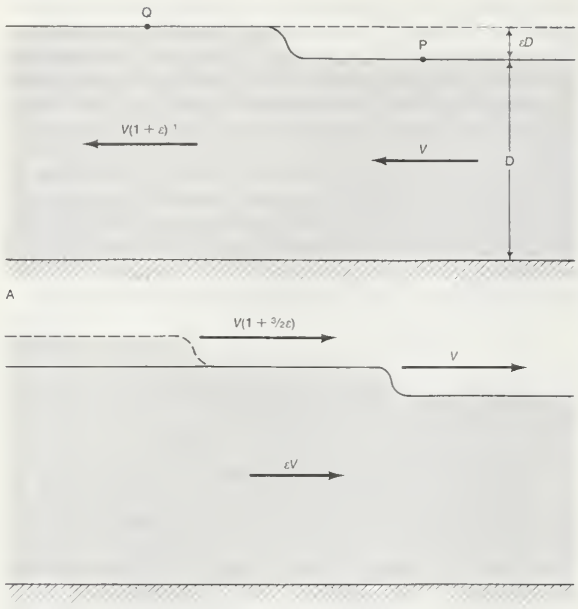

Figure 49: *Steps on the surface of shallow water.* In (A) the water is moving and the step is stationary. In (B) the water is stationary in front of the first step and the step is therefore moving; the second step (dotted line) is catching up to the first.

greater than the depth of the water, D, and provided that its amplitude is very much less than D, a wave travels over stationary water at a speed given by (138). Because their speed does not depend on wavelength, the waves are said to be nondispersive.

Non-dispersive waves

Evidently waves that are approaching a shelving beach should slow down as D diminishes. If they are approaching it at an angle, the slowing-down effect bends, or refracts, the wave crests so that they are nearly parallel to the shore by the time they ultimately break.

Suppose now that a small step of height εD ($\varepsilon << 1$) is traveling over stationary water of uniform depth D and that behind it is a second step of much the same height traveling in the same direction. Because the second step (suggested by a dotted line in Figure 49B) is traveling on a base that is moving at $\varepsilon\sqrt{(gD)}$ and because the thickness of that base is $(1 + \varepsilon)D$ rather than D, the speed of the second step is approximately $(1 + 3\varepsilon/2)\sqrt{(gD)}$. Since this is greater than $\sqrt{(gD)}$, the second step is bound to catch up with the first. Hence, if there are a succession of infinitesimal steps that raise the depth continuously from D to some value D', which differs significantly from D, then the ramp on the surface is bound to become steeper as it advances. It may be shown that if D' exceeds about $1.3D$, the ramp ultimately becomes a vertical step of finite height and that the step then "breaks." A finite step that has broken dissipates energy as heat in the resultant foaming motion, and Bernoulli's equation is no longer applicable to it. A simple argument based on conservation of momentum rather than energy, however, suffices to show that its velocity of propagation is

$$\sqrt{\left(\frac{gD'(D' + D)}{2D}\right)}. \qquad (139)$$

Tidal bores, which may be observed on some estuaries, are examples on the large scale of the sort of phenomena to which (139) applies. Examples on a smaller scale include the hydraulic jumps that are commonly seen below weirs and sluice gates where a smooth stream of water suddenly rises at a foaming front. In this case, (139) describes the speed of the water, since the front itself is more or less stationary.

When water is shallow but not extremely shallow, so that correction terms of the order of $(D/\lambda)^2$ are significant, waves of small amplitude become slightly dispersive (see below *Waves on deep water*). In this case, a localized disturbance on the surface of a river or canal, which is guided by the banks in such a way that it can propagate in one direction only, is liable to spread as it propagates. If its amplitude is not small, however, the tendency to spread due to dispersion may in special circumstances be subtly balanced by the factors that cause waves of relatively large amplitude to form bores, and the result is a localized hump in the surface, of symmetrical shape, which does not spread at all. The phenomenon was first observed on a canal near Edinburgh in 1834 by a Scottish engineer named Scott Russell; he later wrote a graphic account of following on horseback, for well over a kilometre, a "large solitary elevation . . . which continued its course along the channel apparently without change of form." What Scott Russell saw is now called a soliton. Solitons on canals can have various widths, but the smaller the width the larger the height must be and the faster the soliton travels. Thus, if a high, narrow soliton is formed behind a low, broad one, it will catch up with the low one. It turns out that, when the high soliton does so, it passes through the low one and emerges with its shape unchanged (see Figure 50).

Solitons

It is now recognized that many of the nonlinear differential equations that appear in diverse branches of physics have solutions of large amplitude corresponding to solitons and that the remarkable capacity of solitons for surviving encounters with other solitons is universal. This discovery has stimulated much interest among mathematicians and physicists, and understanding of solitons is expanding rapidly.

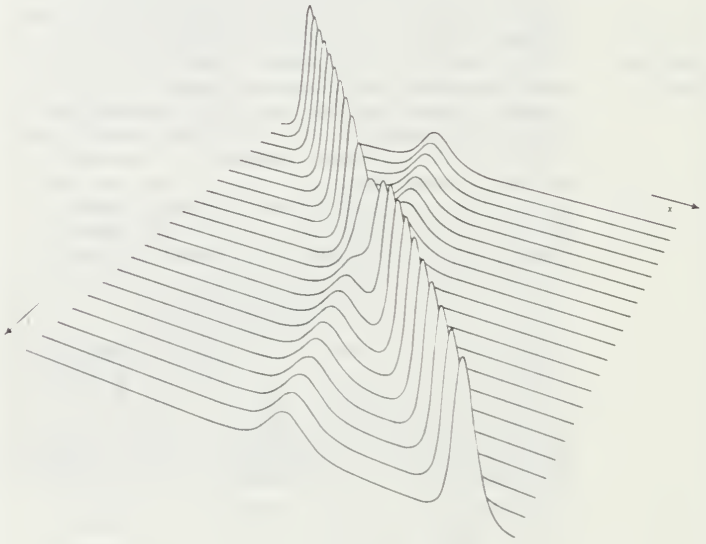

Figure 50: Interaction of two solitons (see text).

COMPRESSIBLE FLOW IN GASES

Compressible flow refers to flow at velocities that are comparable to, or exceed, the speed of sound. The compressibility is relevant because at such velocities the variations in density that occur as the fluid moves from place to place cannot be ignored.

Flow at velocities equal to or greater than the speed of sound

Suppose that the fluid is a gas at a low enough pressure for the ideal equation of state, equation (118), to apply and that its thermal conductivity is so poor that the compressions and rarefactions undergone by each element of the gas may be treated as adiabatic (see above). In this case, it follows from equation (120) that the change of density accompanying any small change in pressure, dp, is such that

$$\rho^{-1}dp = \left(\frac{\gamma}{\gamma - 1}\right)d\left(\frac{p}{\rho}\right). \qquad (140)$$

This makes it possible to integrate the right-hand side of equation (131), and one thereby arrives at a version of Bernoulli's law for a steady compressible flow of gases which states that

$$\frac{\gamma p}{(\gamma - 1)\rho} + \frac{v^2}{2} + gz \qquad (141)$$

is constant along a streamline. An equivalent statement is that

$$\frac{C_p T}{M} + \frac{v^2}{2} + gz \qquad (142)$$

is constant along a streamline. It is worth noting that, when a gas flows through a nozzle or through a shock front (see below), the flow, though adiabatic, may not be reversible in the thermodynamic sense. Thus the entropy of the gas is not necessarily constant in such flow, and as a consequence the application of equation (120) is open to question. Fortunately, the result expressed by (141) or (142) can be established by arguments that do not involve integration of (131). It is valid for steady adiabatic flow whether this is reversible or not.

Bernoulli's law in the form of (142) may be used to estimate the variation of temperature with height in the Earth's atmosphere. Even on the calmest day the atmosphere is normally in motion because convection currents (see below *Convection*) are set up by heat derived from sunlight that is released at the Earth's surface. The currents are indeed adiabatic to a good approximation, and their velocity is generally small enough for the term v^2 in (142) to be negligible. One can therefore deduce without more ado that the temperature of the atmosphere should fall off in a linear fashion—*i.e.*, that

$$T(z) = T(0) - \beta z = T(0) - \left(\frac{Mg}{C_p}\right)z. \qquad (143)$$

Lapse rate

Here β is used to represent the temperature lapse rate, and the value suggested for this quantity, (Mg/C_p), is close to 10° C per kilometre for dry air.

This prediction is not exactly fulfilled in practice. Within the troposphere (*i.e.*, to the heights of about 10 kilometres to which convection currents extend), the mean temperature does decrease with height in a linear fashion, but β is only about 6.5° C per kilometre. It is the water vapour in the atmosphere, which condenses as the air rises and cools, that lowers the lapse rate to this value by increasing the effective value of C_p. The fact that the lapse rate is smaller for moist air than for dry air means that a stream of moist air which passes over a mountain range and which deposits its moisture as rain or snow at the summit is warmer when it descends to sea level on the other side of the range than it was when it started. The foehn wind of the Alps owes its warmth to this effect.

The variation of the pressure of the atmosphere with height may be estimated in terms of β, using the equation

$$p(z) = p(0)\left[1 - \frac{\beta z}{T(0)}\right]^{Mg/R\beta}. \qquad (144)$$

This is obtained by integration of (123), using (118) and (143).

Determining the speed of sound in gases

In the form of equation (141), Bernoulli's law may be used to calculate the speed of sound in gases. The argument is directly analogous to the one applied in the previous section to waves on shallow water—and, indeed, the diagrams in Figure 49 can serve to illustrate the argument here too, if they are regarded as plots of gas density (or else of pressure or temperature, which go hand in hand with density in adiabatic flow) versus position. The results of the argument will be stated without proof. If there exists an infinitesimal step in the density of the gas, it will remain stationary provided that the gas flows uniformly through it toward the region of higher density, with a velocity

$$V_s = \sqrt{\left(\frac{\gamma p}{\rho}\right)}. \qquad (145)$$

If the gas is stationary, then (145) describes the velocity with which the step moves. It also describes the speed of propagation of the sort of undulatory variation of density that constitutes a sound wave of fixed frequency or pitch. Because the speed of sound is independent of pitch, sound waves, like waves on shallow water, are nondispersive. This is just as well. It is only because there is no dispersion that one can understand the words of a distant speaker or listen to a symphony orchestra with pleasure from the back of an auditorium as well as from the front.

It should be noted that the formula for the speed of sound in gases may be proved in other ways, and Newton came close to it a century before Bernoulli's time. However, because Newton failed to appreciate the distinction between adiabatic and isothermal flow, his answer lacked the factor γ occurring in (145). The first person to correct this error was Pierre-Simon Laplace.

The above statements apply to density steps or undulations, the amplitude of which is infinitesimal, and they need some modification if the amplitude is large. In the first place it is found, as for waves on shallow water and for very much the same reasons, that, where two small density steps are moving parallel to one another, the second is bound to catch up with the first. It follows that, if there exists a propagating region in which the density rises in a continuous fashion from ρ to ρ', where $(\rho' - \rho)$ is not necessarily small, then the width of this region is bound to diminish as time passes. Ultimately a shock front develops over which the density—and hence the pressure and temperature—rises almost discontinuously. There are processes within the shock front, vaguely analogous on the molecular scale to the foaming of a breaking water wave, by which energy is dissipated as heat. The speed of propagation, V_{sh}, of a shock front in a gas that is stationary in front of it may be expressed in terms of V_s and V_s', the velocities of small-amplitude sound waves in front of the shock and behind it, respectively, by the equation

$$2V_{sh}^2 = \left[\frac{(\gamma+1)\rho'}{\gamma\rho}\right]V_s'^2 + V_s^2. \qquad (146)$$

Thus, if the shock is a strong one ($\rho' >> \rho$), V_{sh} may be significantly greater than both V_s and V_s'.

Even the gentlest sound wave, in which density and pressure initially oscillate in a smooth and sinusoidal fashion, develops into a succession of weak shock fronts in time. More noticeable shock fronts are a feature of the flow of gases at supersonic speeds through the nozzles of jet engines and accompany projectiles that are moving through stationary air at supersonic speeds. In certain circumstances when a supersonic aircraft is following a curved path, the accompanying shock wave may accidentally reinforce itself in places and thereby become offensively noticeable as a "sonic boom," which may break windowpanes and cause other damage. Strong shock fronts also occur immediately after explosions, of course, and when windowpanes are broken by an explosion, the broken glass tends to fall outward rather than inward. Such is the case because the glass is sucked out by the relatively low density and pressure that succeed the shock itself.

The diagrams in Figure 51 show a well-known construction attributed to the Austrian physicist Ernst Mach that explains the origin of the shock front accompanying a supersonic projectile. The circular arcs in this figure represent cross sections through spherical disturbances that are spreading with speed V_s from centres (S′, S″, etc.), which mark the position of the moving source S at the time when they were emitted. If the source is something like the tip of

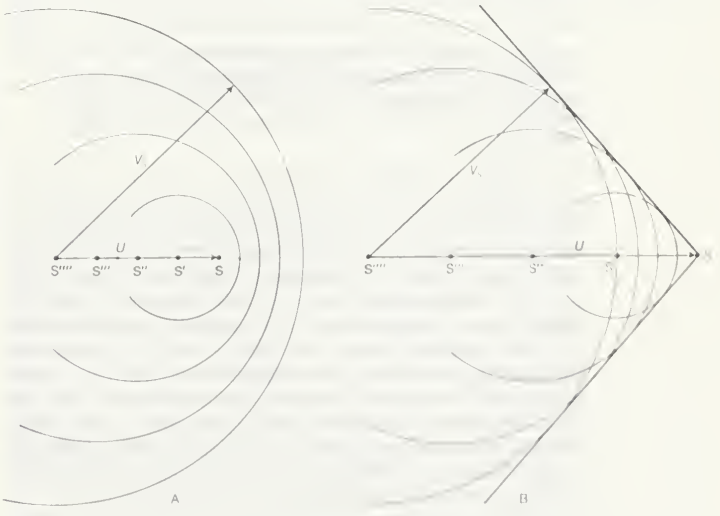

Figure 51: *Mach's construction.*
(A) Source speed U less than speed of sound V_S, (B) U greater than V_S (see text).

an arrow, which disturbs the air by parting it as it travels along but which is inaudible when stationary, then each "disturbance" due to some infinitesimal displacement of the tip is a spherical shell of infinitesimal thickness within which a small radial velocity has been imparted to the air. There is an infinite number of such disturbances, overlapping one another, of which only a handful are represented in Figure 51. When the velocity of the source, U, is less than V_s (Figure 51A), the result of adding them together is the sort of steady backflow that is to be expected around a moving obstacle, and there is no sound emission in the normal sense; the source remains inaudible. When U exceeds V_s, however, the spherical disturbances reinforce one another, as Figure 51B shows, on a conical caustic surface, which makes an angle of $\sin^{-1}(U/V)$ to the line of travel of the source, and it is on this surface that a shock front is to be expected. The cone becomes sharper as the source speeds up.

VISCOSITY

As shown above, a number of phenomena of considerable physical interest can be discussed using little more than the law of conservation of energy, as expressed by Bernoulli's law. However, the argument has so far been restricted to cases of steady flow. To discuss cases in which the flow is not steady, an equation of motion for fluids is needed, and one cannot write down a realistic equation of motion without facing up to the problems presented by viscosity, which have so far been deliberately set aside.

Stresses in laminar motion

The concept of viscosity was first formalized by Newton, who considered the shear stresses likely to arise when a fluid undergoes what is called laminar motion with the sort of velocity profile that is suggested in Figure 52A; the laminae here are planes normal to the x_2-axis, and they are moving in the direction of the x_1-axis with a velocity v_1, which increases in a linear fashion with x_2. Newton suggested that, as each lamina slips over the one below, it exerts a sort of frictional force upon the latter in the forward direction, in which case the upper lamina is bound to experience an equal reaction in the backward direction. The strength of these forces per unit area constitutes the

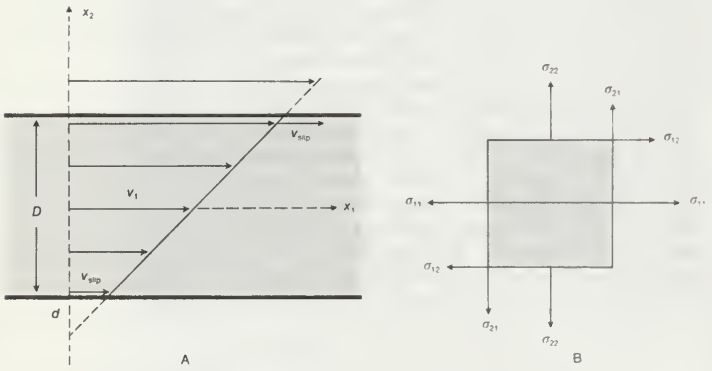

Figure 52: *Laminar motion and associated stresses.* (A) Velocity profile for laminar flow between two plates, driven by motion of the upper plate, (B) an enlarged view of a cubic element of the fluid between the plates, showing the stresses that act upon it.
